SCIENCE

A WEEKLY JOURNAL

DEVOTED TO THE ADVANCEMENT OF SCIENCE.

EDITORIAL COMMITTEE: S. NEWCOMB, Mathematics; R. S. WOODWARD, Mechanics; E. C. PICKERING, Astronomy; T. C. MENDENHALL, Physics; R. H. THURSTON, Engineering; IRA REMSEN, Chemistry; J. LE CONTE, Geology; W. M. DAVIS, Physiography; O. C. MARSH, Paleontology; W. K. BROOKS, C. HART MERRIAM, Zoology; S. H. SCUDDER, Entomology; C. E. BESSEY, N. L. BRITTON, Botany; HENRY F. OSBORN, General Biology; C. S. MINOT, Embryology, Histology; H. P. BOWDITCH, Physiology; J. S. BILLINGS, Hygiene; J. MCKEEN CATTELL, Psychology; DANIEL G. BRINTON, J. W. POWELL, Anthropology.

NEW SERIES. VOLUME VI.

JULY-DECEMBER, 1897.

NEW YORK
THE MACMILLAN COMPANY
1897

THE NEW ERA PRINTING COMPANY,
41 North Queen Street,
Lancaster, Pa.

CONTENTS AND INDEX.

N. S. VOL. VI—JULY TO DECEMBER, 1897.

The Names of Contributors are Printed in Small Capitals.

ABBOTT, A. C., System der Bakterien, Wm. Migula, 964
Acetylene Gas, 444; Restrictions applied to Manufacture and Storing of, 877
Achelis, Thomas, Relations of Mythology to Ethnography, 440
ADAMS, FRANK D., Explorations in the Labrador Peninsula, A. P. LOW, 741
ADLER, CYRUS, International Catalogue of Scientific Literature, 184
Agonoid Genus Percis of Scopoli, THEO. GILL, 958
Agriculture, U. S. Department of, Year-book of the, T. D. A. COCKERELL, 411; Report of the Secretary of, 697; and Forestry, British Board of, 840
Air, Rarefied and Condensed, G. VON LIEBIG, 157
Alchemy, The Revival of, H. CARRINGTON BOLTON, 832
Alcohol, Practical Teaching of the Physiology of, 559; Consumption of, in France, 701
Allen and Horn, Memorial Meeting Commemorative of, 997
Allen, E. T., Native Iron from Coal Measures of Missouri, 588
ALLEN, J. A., and ELLIOTT COUES, The Merton Rules, 9
American, Association for the Advancement of Science, 56, 166, 181, 217, 287; Proceedings of the, ASAPH HALL, JR., 283; and British Association for the Advancement of Science, The Meetings of, 377; Chemical Journal, J. ELLIOTT GILPIN, 331, 968; Naturalist, 482, 708, 888; Journal of Science, 708, 888
Americanistas, Congreso, Internacional de, D. G. BRINTON, 777
Amphibia vs. Batrachia, G. BAUR, 170, 372; BURT G. WILDER, 295; THEO. GILL, 446; O. P. HAY, 773
Anatomical Society, German, 95
Anderson on Stomata in Abies pectinata, 574
Andrée's North Pole Balloon Voyage, H. A. HAZEN, 373
Andrews, Gwendolen Foulke, The Living Substance as Such and as Organism, 964
Angiosperms, Phylogeny and Taxonomy of the, CHARLES E. BESSEY, 398
Année, Sociologique, 991
Anthropological, Society, German, 127; Section at Toronto, E. W. CLAYPOLE, 450; Society of Washington, J. H. MCCORMICK, 967
Anthropology, Current Notes on, D. G. BRINTON, 22, 54, 124, 164, 207, 248, 287, 316, 359, 403, 439, 657, 695, 728, 762, 803, 836, 873, 910, 952, 987; Physical, GEORGE A. DORSEY, 109; and Ethnology of Europe, Bibliography of, 321; at the American Association for the Advancement of Science, ANITA NEWCOMB MCGEE, 508; at the Toronto Meeting of the British Association, A. F. CHAMBERLAIN, 575; and Psychology, N. Y. Academy of Sciences, C. P. BLISS, 779
Anthropometric Measurements in Schools, 579
Anti-toxin Treatment of Diphtheria, 130
Apstein, Carl, Das Süsswasserplankton, C. A. KOFOID, 140
Archæological Society, Swiss, Excavations of, 914
Arctic Exploration, Review of, 845
Argentina, Scientific Society of, 318
ASHMEAD, WM. H., Section of the Zoology of the A. A. A. S., 433
Ashmead, Wm. H., North American Species of Ceresa, 435
Astronomical Reports at Oxford and at the Cape, 129
Astronomy, Aspects of American, SIMON NEWCOMB, 709
Astrophysical, Notes, E. B. FROST, 587; Research, The Importance of, and the Relation of Astrophysics to other Physical Sciences, JAMES E. KEELER, 745; Journal, 888
ATKINSON, GEORGE F., Experimental Morphology, 538; Physiology of Plants, Paul Sorauer, 810.
Atlantic Monthly, 520
Atomic Models, 26
Atwater, W. O., and E. B. Rosa, Conservation of Energy in the Human Body, 653
Auk, Great, Eggs of the, 767
Australasian Association for the Advancement of Science, 28, 252, 483, 701, 878
Automobile Club of Great Britain, 957
Ayrton and Mather on Galvanometers, 471

Bailey, Frederick H., and Frederick S. Woods, Plane and Solid Analytic Geometry, F. N. COLE, 959
Bailey, L. H., Principles of Fruit Growing, 321
BAILEY, VERNON, Wild Neighbors, Ernest Ingersoll, 921
Bain on the Three Drift Sheets of Iowa, 438
Baker, F. C., Gasteropod Mollusks, 108
BALDWIN, J. MARK, Determinate Variation and Organic Selection, 770
Balfour, H., on the Aghori Fakirs, 165
Ball, John, Solution of Zinc in Dilute Acids, 125
Balneology, International Congress of, 956.
BARNES, C. R., Botanical Society of America, 401
Barrois, Charles, Geography of Brittany, 23
BARUS, CARL, A Clamp for Fragile Glassware, 31; Long Range Temperature and Pressure Variables in Physics, 338
Bassariscus Raptor (Baird), Correction Concerning

Mr. Rhoads' Use of the Name, C. HART MERRIAM, 174
Bauer, L. A., Secular Motion of the Earth's Magnetic Axis, 757 ; Diurnal range of Magnetic Declination and Inclination, 757
BAUR, G., Amphibia or Batrachia, 170, 372
Beaver, Protection of the, 807
BECKER, GEORGE F., Lewis on the Diamond, 664 ; New Diamond Find in the Transvaal, 726
BEDELL, FREDERICK, The Alternating Current Circuit, W. Perren Maycock, 883
Bedell, F., Predetermination of Transformer Regulation, 653
Behrens, H. v., Mikrochemische Analyse, E. R., 884
Belgium Royal Academy, 732
BELL, ALEXANDER GRAHAM, A Brilliant Meteor, 99
BEMAN, W. W., A Chapter in the History of Mathematics, 297
BENJAMIN, MARCUS, British and American Associations, 775
Bering Sea Conferences, Results of the, 781 ; P. L. SCLATER, 994
Berlin Academy of Sciences, 94
Berthelot, and Vieille, on the Storage of Acetylene, 56 ; Chemistry of Glass Mirrors, 874
BESSEY, CHARLES E., Phylogeny and Taxonomy of the Angiosperms, 398 ; Botanical Notes, 622, 696, 836
Bessey, C. E., The Botanical Survey of Nebraska, 573 ; Rhus radicans, 885
Bigelow, Frank H., Standard Systems of Notation in Mathematics and Physics, 758
Biles on Improved Materials of Construction, 56
Billings, John S., Report on the Vital and Social Statistics in the United States, T. D. A. COCKERELL, 174
Billroth, Monument to, 839
Biological, Society of Washington, F. A. LUCAS, 671 ; 707, 814, 886, 966 ; Station in Jamaica of Johns Hopkins University, 480 ; Expedition of New York University to the Bermudas, CHARLES L. BRISTOL, 724
Biology, Section of, New York Academy of Sciences, C. L. BRISTOL, 107 ; GARY N. CALKINS, 851
Birds, Protection of, 292
Blind and Deaf, Report of the British Council on Education for the, 445
BLISS, C. P., Anthropology and Psychology, N. Y. Academy, 779
BOAS, FRANZ, Totem Tales, W. S. Phillips, 778; Anthropologische Studien ueber die Ureinwohner Brasiliens, Paul Ehrenreich, 880
Boas, Franz, Primitive Art Motives, 287 ; Growth of Toronto School Children, 579 ; Northwestern Tribes of Canada, 579
Bokorny, Th., on Antiseptics, 250
BOLTON, H. CARRINGTON, Revival of Alchemy, 853
Bolton, H. Carrington, Recent Progress of Alchemy in America, 360 ; Early American Chemical Societies, 763 ; Hysterical Chemistry, 965
Bond, William Cranch, Memorials of, 408,
Born G., Ueber Verwachsungsversuche mit Amphibienlarven, CHARLES S. MINOT, 704
Boston, Guide Book to Region round, 767 ; Society of Natural History, SAMUEL HENSHAW, 816, 922, 1003
Botanic Society, Royal, 322
Botanical, Society of America, C. R. BARNES, 401 ; Garden of New York, 555 ; Excursion to Mexico, JOHN W. HARSHBERGER, 569 ; Notes, C. E. BESSEY, 622, 696, 836 ; Activity in Japan, 622 ; Garden, New York, Boston Plans for a, N. Y., 632 ; Gazette, 780
Botany, of the British Association, D. P. P., 472 ; a the American Association for the Advancement of Science, F. C. NEWCOMBE, 572
Bowditch, H. P., Rhythm of Smooth Muscles, 550
Brain, the Desirability and the Feasibility of Some Accurate Knowledge of the, by Pre-collegiate Scholars, BURT G. WILDER, 902
BRANNER, J. C. New Terms in Geology and Geography, 133
Breul on Pigmentation of the Skin, 124
Briggs, Lyman J., Water Movement in Soils, 966
BRINTON, D. G., Current Notes on Anthropology, 22, 54, 124, 164, 207, 248, 287, 316, 359, 403, 439, 657, 695, 728, 762, 803, 836, 873, 910, 952, 987 ; L'evolution de commerce dans les diverses races humaines, Ch. Letourneau, 742 ; Congreso Internacional de Americanistas, 777 ; Anthropologische Studien über die Ureinwohner Brasiliens, Paul Ehrenreich, 879? Das Nördliche Mittel-Amerika, nebst einen Ausflug nach den Hochland von Anahuac, 920; The History of Mankind, Friedrich Ratzel, 961
BRISTOL, C. L., New York Academy of Sciences, Section of Biology, 107 ; Alumni Biological Expedition of New York University to the Bermudas, 724
British Association, Toronto Meeting of the, 333 ; A. B. MACALLUM, 201, 318 ; Grants for Scientific Research, 554; Address of the President, SIR JOHN EVANS, 269; and American Associations for the Advancement of Science, the Meetings of the, 377, MARCUS BENJAMIN, 775
Britton, E. G., Moss Flora of the Adirondack Mountains, 70 ; Ophioglossum, 1004
Britton, N. L., and Addison Brown, Illustrated Flora of the Northern United States, Canada and the British Possessions, F. V. COVILLE, 179
Brown on Cathode Rays, 470
Brush, Chas. F., Transmission of Radiant Heat by Gases at Varying Pressures, 649
Brückner's Erdrinde und ihre Formen, 872
Bruyn, Lobry de, The Genesis of Petroleum, 838
BUCHANAN, GEORGE CHAS., Oysters : A Review of Ignorance, 137
BUCHNER, EDWARD F., Observations on the Principle of Identity, 809
Bügsen, M., Bau und Leben unserer Waldbäume, B. E. FERNOW, 962
BUMPUS, HERMON C., Habit and Instinct, C. Lloyd Morgan, 918
BURCKHARDT, RUD., Ludwig Rütimeyer, 985
BURGESS, EDWARD S., Torrey Botanical Club, 36, 70, 924, 967, 1004
Butler, A. W., Indiana, W. T. DAVIS, 260

Calcium carbide, 404
CALKINS, GARY N., Columbia University Zoological Expedition of 1897, 513 ; New York Academy of Sciences, Section of Biology, 851
CALLENDAR, HUGH L., Mathematics and Physics at the British Association, 464
Callendar, H. L., and H. T. Barnes, Specific Heat of Liquid in terms of the International Electrical Units, 466 ; The B. O. T. Form of Standard Cell,

471; and N. N. Evans, On the Behavior of Argon in X-Ray Tubes, 469
Canning Industries, Contribution to our Knowledge of the Micro-organisms and Sterilizing Processes in the, S. C. PRESCOTT, W. LYMAN UNDERWOOD, 800
Card Catalogue, New Form of, 131
Carhart, H. S., A Watt Transformer, 650
Caribs, Central American, 24
Catalogue, International, of Scientific Literature, CYRUS ADLER, 184
CATTELL, J. MCKEEN, The Chances of Death and other Studies in Evolution, Karl Pearson, 328; Sight, Joseph Le Conte, 491; The Alleged Extinction of Lines of Descent, 668
Cattell, J. McKeen, A Statistical Study of Eminent Men, 512
Cerebral Light, E. W. SCRIPTURE, 138; JOSEPH LE CONTE, 257
Ceylon, Geological and Topographical Survey of, 841
CHAMBERLAIN, A. F., Anthropology at the Toronto Meeting of the British Association, 575
Chamberlain, A. F., Kootenay Indian Drawings, 580
Chamberlain, W. E., G. F. Weida and W. Bromwell, Decomposition of Diazo Compounds, 143
Characters, Congenital and Acquired, G. ARCHDALL REID, 896, 933
Chemical, Society, American, N. Y. Section, DURAND WOODMAN, 35, 672, 779; of Washington, V. K. CHESNUT, 69, 965; Journal, American, J. ELLIOTT GILPIN, 143; Literature, Fifteenth Annual Report of the Committee on Indexing, 761; Congress, International, 765
Chemistry, Inorganic, Notes on, J. L. H., 25, 55, 124, 165, 208, 249, 317, 360, 404, 440, 478, 588, 623, 658, 729, 763, 804, 838, 874; at the British Association, W. W. R., 614; International Congress for Applied, 876
CHESNUT, V. K., Chemical Society of Washington, 69, 965
Chesnut, V. K., Mushroom Poisoning, 886
Child, C. D., Discharge of Electrified Bodies by X-rays, 650
Child Study, Minnesota Association for, 520
Chuard, E., Calcium Carbide, 125
Clamp for Fragile Glassware, CARL BARUS, 31
CLARK, W. B., The Founders of Geology, Sir Archibald Geikie, 925
CLAYPOLE, E. W., The Anthropological Section at Toronto, 450
Coal Production in the United States, 98
Coast and Geodetic Survey, Field Work of the, P., 436, 699; Appointment of H. S. Pritchett, 699, 877
COCKERELL, T. D. A., The Present Evolution of Man, G. Archdall Reid, 33; Report on Vital and Social Statistics in the United States, John S. Billings, 174; Year-book of the U. S. Department of Agriculture, 411; The Present Evolution of Man, 562; More Dictionary Zoology, 633
COLBURN, RICHARD T., Diversity of Languages, 682
COLE, F. N., The American Mathematical Society, 356; Elements of Plane and Spherical Trigonometry, Edwin S. Crawley, 958; Numerical Problems in Plane Geometry, J. G. Estill, 959; Plane and Solid Geometry, Frederick H. Bailey and Frederick S. Woods, 959
Color Standards, W. HALLOCK and R. GORDON, 214
Colors, a Simple Method of Combining the, F. W. MCNAIR, 740
Colorado, Antecedent, MARK S. W. JEFFERSON, 293
Comstock, J. H., Insect Life, S. W. W., 670
Cook, O. F., A New Wingless Fly from Liberia, 886
Cooke, W. W., Birds of Colorado, W. H. OSGOOD, 707
COOPER, H. C., The Death of Victor Meyer, 449
Cope, Edward Drinker, A Chapter in the History of Science, THEO. GILL, 225; Memorial Meeting, 731
COPLIN, W. M. L., A New Laboratory Dish, 476
Coral Atoll of Funafuti, 482
Cordite, Disputed Originality of Invention of, 250
Cory, Charles B., Shore Birds of North America; Ducks, Geese and Swans of North America, C. H. M., 742
Cosmopolitan University, 448
COUES, ELLIOTT, and J. A. ALLEN, The Merton Rules, 9
COVILLE, F. V., Illustrated Flora of the Northern United States, Canada and the British Possessions, N. L. Britton and Addison Brown, 179
Coville, Frederick V, Botany of the Klamaths, 404.
Cowper, H. S., Wadis of Tripoli, 286
CRAGIN, F. C., Fossils of the Comanche Series, 134
Crawley, Edwin S, Elements of Plane and Spherical Trigonometry, F. N. COLE, 958
CREIGHTON, J. E., The Philosophy of Knowledge, George Trumbull Ladd, 597
Crime Statistics in Egypt, 736
Cripps, R. A., Boric Acid and Digestive Ferments, 440
Crook, A. R., Scenery of Yellowstone Park, 657
Crookes, William, on Diamonds, 249
Crossley Reflector of Lick Observatory, Trial of the, EDWARD S. HOLDEN, 32
Croustchoff on Russium, 317
Curtiss, R. S., Malonic Acid Derivatives, 332
Cushing, F., Genesis of Implement Making, 583
Czernik, G. C., Gases in Minerals, 588

Dahlias of Mexico, JOHN W. HARSHBERGER, 908
DALL, WM. H., Dangers of Formalin, 633
Darwin, Francis, Stomata, 474
DAVENPORT, C. B., The Term 'Internal Secretions,' 215.
Davis on the Variation of Trillium grandiflorum, 592
DAVIS, BRADLEY M., The Vegetation of the Hot Springs of Yellowstone Park, 145
DAVIS, W. M., Current Notes on Physiography, 22, 93, 206, 285, 357, 438, 656, 727, 834, 872, 985; Is the Denver Formation Lacustrine or Fluviatile? 619.
Davis, W. M., Coastal Plain of Maine, 618
DAVIS, W. T., Indiana, A. W. Butler, 260
Dawson, G. M., A Handbook of Canada, 728
Deaf, Education of the, 560
Dean, Bashford, Palæospondylus, 852
Deaths: Harrison Allen, 764; William Archer, 519; L. Auerbach, 700; J. F. Babcock, 167; James Bateman, 955; S. E. Beal, 481; Oscar Boer, 211; V. Bogdanowskaja-Popoff, 96; T. Bogomoloff, 519; Konrad Bohn, 591; R. Branchat, 700; Samuel Brassai, 127; Anthony Brownless, 955; Sir John Bucknell, 211; M. Chudzinski, 167; Charles E. Colby, 628; Joseph G. C. Cottier, 363; C. F. Crocker, 167; Edmund Drechsel, 628;

Raphael v. Erlanger, 990; G. Fissore, 167; John Foster, 660; E. P. Franz, 660; Alexander Freeman, 28; Ernest Giles, 914; Dr. Golowkinskie, 252; E. L. Gros, 167; R. P. H. Haidenhain, 628; M. Forster Heddle, 876; Hjalmar Heiberz, 700; J. B. Hicks, 519; Dr. Holmgren, 519; George H. Horn, 839; Samuel Houghton, 839; G. G. Hubbard, 913; J. E. Humphrey, 363; Wilhelm Joest, 990; A. S. Kimball, 876; Johann Ritter von Leich, 211; Victor T. di S. Leon, 96; J. B. Luys, 405; Theodore Lyman, 442; W. Marmé, 167; Albert Marth, 364; Alfred M. Mayer, 94; Edgar McClure, 211; Victor Meyer, 319; Dr. Mietscke, 700; Everett Millais, 481; A. M. Edler v. Mojsvar, 519; Alfred Moquart, 96; Campbell Morfit, 914; A. J. Mundella, 211; Armino Nobile, 211; M. Josef Oertel, 167; Mark Olivet, 665; W. Petzold, 319; W. T. Preyer, 252; Franz Pulszky, 443; M. Quantin, 319; P. Le P. Renouf, 700; A. M. Ross, 700; C. P. Roy, 591; Julius von Sachs, 28; Henry W. Sage, 481; F. C. Schneider, 990; Dr. Schrauff, 990; P. Schützenberger, 96; B. L. Sclater, 252; William Scott, 660; F. W. Snyder, 990; Japetus Steenstrup, 58; W. A. Stiles, 591; Dr. Stoll, 628; I. N. Travis, 405; J. H. Trumbull, 252; Peter von Tunner, 28; Étienne Vacherot, 252; H. Wankel, 127; Herman Welcker, 591; Martin Wilckens, 96; Justin Winsor, 660; De Volson Wood, 28

Denver Formation, Is it Lacustrine or Fluviatile? W. M. DAVIS, 619

Descent, Lines of, The Alleged Extinction of, J. McKEEN CATTELL, 668

Detroit and Toronto, International Amenities at, W J McGEE, 380

Diamond, The Genesis of the, GEORGE F. KUNZ, 450; Lewis on the, GEORGE F. BECKER, 664; Find in the Transvaal, GEORGE F. BECKER, 726.

Diller, J. S., Origin of Camas Swale, 923

Discussion and Correspondence, 30, 63, 99, 133, 170, 214, 257, 293, 323, 368, 409, 446, 485, 523, 561, 594, 632, 664, 703, 737, 770, 809, 846, 879, 916, 958, 994

MSS. intended for publication and books, etc., intended for review should be sent to the responsible editor, Prof. J. McKeen Cattell, Garrison-on-Hudson, N. Y.

LIFE AND LETTERS OF WILLIAM BARTON ROGERS.

THE present generation of men and women have shown in an extraordinary degree their interest in the personality of historical characters.

Current literature teems with examples of this interest in biographical sketches without number, and the public seems to enjoy the most trifling details of the lives of persons of distinction, to secure which both the pen and the camera are driven to the last limit.

That this taste has abnormally developed and is in a large measure harmful few will deny, but there will always exist a wholesome curiosity as to the personal qualities of men whose performances have commanded our admiration. It is not alone in political history that biography is so important. To the student of science a knowledge of the temper, spirit, moods or idiosyncrasies of eminent scientific men has always been highly valued, not only on account of its intrinsic interest, but also because such knowledge often assists in a proper interpretation and appraisement of their work. But when distinguished success is to be attributed to personal qualities even more than to talent; when to scientific accomplishments of a high order is joined a personality so charming and so noble as to silence opposition and command approval, anything that reveals, even a small

degree, the motives, inspirations or promptings of such human activity is doubly welcome.

The 'Life and Letters' of Professor W. B. Rogers, edited by his wife with the assistance of Professor W. T. Sedgwick, has recently made its appearance.* The memoir is published in two beautifully printed volumes of about 400 pages each. In the short preface to the first the editors explain that they have been prepared in the hope that they 'may be of some service to the cause of science and education.' Their work has been done with rare wisdom and good taste. It has consisted mainly in providing a continuous yet unobtrusive background of biography, upon which is displayed an extensive and wonderfully interesting series of letters, in which the whole story of the life of Professor Rogers is revealed.

It may be well in the beginning to briefly summarize in their chronological order the principal events of that life. Professor Rogers was born in Philadelphia in 1804. His father was Dr. Patrick Kerr Rogers, who was himself born in Ireland in 1776, the son of Robert Rogers, of Edergole. Mr. P. K. Rogers fled from Ireland on account of articles which he had contributed to the Dublin newspapers in criticism of the action of the government in the matter of the Irish Rebellion of 1798. Coming to Philadelphia he entered the University of Pennsylvania as a tutor, and in 1802 he received the degree of Doctor of Medicine from that institution. A year before graduation from the medical school he married Hannah Blythe, who had come from Glasgow to make her home in America. She died in 1820, leaving four sons, James B., William B., Henry D. and Robert E. Rogers, all of whom became eminent in science and in public life, being frequently spoken of in Europe and in this country as 'the brothers Rogers.'

Dr. P. K. Rogers removed with his family to Baltimore in 1812, and in 1819 he was elected to the chair of natural philosophy, which at that time covered a very broad field, in William and Mary College, Virginia. William was a student here in 1819–20, and there is printed in the memoir an interesting fac simile of a report of the standing of the two sons, James and William, in which, in addition to the statement that they had been 'orderly, diligent and attentive to their studies,' there is an interesting forecast of their career in the declaration that 'in mathematics and chemistry they have made the most flattering improvement.' There is good evidence, some of which is found in the fragments, which have been preserved, of a correspondence with Thomas Jefferson, that Dr. Patrick Rogers was an accomplished mathematician and general scholar and that the tastes and talents of the 'brothers Rogers' were largely inherited. When James, at the early age of 19 years, was studying medicine in Baltimore he wrote to William, aged 17 years, a letter full of criticism of the 'singular views' advanced by one of his professors on the subject of chemical attraction or affinity and the true cause of chemical union. He begs William to give him his own opinion of the matter in an early reply, and concludes with a burst of filial loyalty in the declaration that, although the aforesaid professor is the best lecturer in the institution, the lectures of their father on the same subject as far surpass his work 'in point of correctness, science and elegance as the meridian sun does the evening star in brilliancy.' In a youthful oration given by William on a public occasion in 1822 he foreshadowed, at the age of 18, the eloquence of speech for which he was in later years famous.

* Published by Houghton, Mifflin & Co., Boston, to whom we are indebted for the plate of the portrait accompanying this article.

In 1825 both William and Henry removed to Baltimore to seek their fortunes, but the physical weakness by which they were greatly handicapped and against which they fought during all of their lives interferred with their success from the start. The two brothers finally obtained employment as teachers, but there was frequent necessity for pecuniary aid from the father, who was ever ready to draw upon his slender salary the payments of which were made with much irregularity and often much delay, for the benefit of his sons, of whom he was extremely fond and justly proud.

William began to show his rare qualities as a lecturer on Science, and in 1827 he was appointed to a lectureship in the Maryland Institute. His father died in 1828 and in the same year he was elected as his successor in the chair of natural philosophy at William and Mary, at the early age of 24 years. Here he remained for seven years, growing in knowledge and reputation, and in 1835 he was elected professor of natural philosophy in the University of Virginia, and shortly afterward he was appointed State Geologist. His connection with this institution continued for eighteen years, and its history forms one of the most interesting features of the memoir. During this period the University passed through some of its most notable trials in connection with the relations of its governing authority, the faculty, to the student body. In all of these events, as well as others of more lasting importance to the institution, Professor Rogers was a prominent figure. That he impressed himself in a notable way upon the then young and developing University was always recognized by its officers and friends. That his connection with it, and especially his long life in the South, covering as it did his youth and the most impressionable years of his manhood, did much to influence his educational ideas as well as his personality, is equally true. Indeed, there was always in his manner something of that courtliness and chivalry which we are wont to associate with the cultivated Southern gentleman and when transplanted to New England it became one of his principal charms. During his life in Virginia his fame as a lecturer and scientific investigator grew continually. He was invited to lecture in various cities, and just previous to his leaving the South Professor Henry solicited his assistance in a course to be given 'for the benefit of Congress' at the Smithsonian Institution.

In 1849 he married Miss Emma Savage, of Boston, going with her to Europe, where some pleasant months were spent and valuable acquaintances formed or renewed, and returning to the University of Virginia in October of the same year. In 1853 he resigned his professorship and removed to Boston, where his wife had lived and where her family and friends were, and also where his brother Henry had already met with such generous support and assistance in his scientific work. Here, for a period of nearly ten years, he worked, wrote and lectured, all the time keeping in mind the organization and development of a school of technology or applied science, the plans for which had been in his mind since at least as early as 1846. On April 10, 1861, the Act incorporating the Massachusetts Institute of Technology received the approval of Governor Andrew, just as the Nation was plunging into what proved to be a mighty struggle for its existence. A year later he was formally elected President of the Institute, which as yet had no material existence. Indeed the war for the preservation of the Union delayed the consummation of his desires until October, 1865, at which time instruction in the new school was actually begun.

In 1868 Professor Rogers began to show the effects of the years of devoted activity which had resulted so fortunately as far as

the school was concerned, his always rather delicate health giving way to such an extent as to make a prolonged period of rest imperative. Accordingly he resigned his presidency of the Institute in 1870, and lightened his labors as much as was possible. In 1876 he presided over the meeting of the American Association for the Advancement of Science in Buffalo, a meeting which was distinguished by the attendance of many foreign savants who were drawn to this country by the Centennial Exposition, held that year in Philadelphia. He had been specially chosen by his fellows to preside on that occasion, because of their desire to put forward the best available representation of American science.

In 1878, on the resignation of Professor Runkle, who had succeeded him as President of the Institute of Technology, he was induced to accept that office again, with the understanding that his holding should be but temporary. In 1879 he was elected by the National Academy of Sciences to succeed Professor Henry as its President, the highest honor which can be conferred upon a man of science in this country. In 1881 he again resigned his presidency of the Institute of Technology, General Francis A. Walker having been selected by him and appointed on his recommendation as his successor. A year later, at noon of May 30, 1882, came his tragic death. In the midst of an address to the graduating class of the Institute, in which his hearers were delighted with an apparent revival of the spirit and eloquence with which he was accustomed to enrich every occasion for dignified address, he fell upon the platform of Huntington Hall, surrounded by the material realization of his dreams of nearly forty years earlier and by those who by the closest associations had learned to love him as few are loved in these days.

Fit into this skeleton sketch the interesting letters which happily have been preserved, mostly being correspondence with his brothers or family friends, and the story of his long and useful life will be fairly well told, although to form an adequate idea of his accomplishments in science and education one must consult the appendices to the two volumes where will be found a list of his scientific publications and one or two of his more important educational papers. I may venture, however, to give the reader of this notice a little taste of what the volumes have in store for him, and at the same time illustrate the remarkable biographical value of the published letters by quoting from a few of them.

Mention has been made of his power as a lecturer on scientific subjects and of his ability to stir with eloquence even when comparatively dry and interesting material was under discussion. One of his early pupils at the University of Virginia says of him that he was endowed with "not alone an imagination which ever clothed truth with beauty and made the dullest fact radiant with a significance illimitable and imperishable, but also every personal gift which can enhance the power of the orator. Tall in stature, with a figure of the type known to us through the pictures of Henry Clay; with a face that, destitute of all assumption or arrogance, was singularly commanding; with a voice whose compass and quality were capable of producing at once the largest and the finest effects of speech, William Barton Rogers was, in the height of his powers, without a peer among the scientific men of his age in addressing an intelligent and cultivated audience." This remarkable *faculty for teaching* was appreciated by all who came in contact with him. Theodore Parker wrote to him in 1859, when just on the point of starting for London: * * * * * * "I return Mr. Owen's remarkable pamphlet. What an instructive thing it is!

"I should have been surprised that it could all have come from one man if I had not known yourself and your brother, who in such matters taught me the *nil admirari.* * * * Allow me to thank you for the instruction I have received from you, and for the many friendly and noble words you have spoken to me. My acquaintance with you began with your brother, and I feel gratitude to you both. For you both turn your deep, wide science into humanity. I have found you both always on the side of mankind and feel strengthened and encouraged by your example." Wherever and whenever good speaking was understood and appreciated Professor Rogers was in demand. When in England, in 1849, he attended the annual meeting of the British Association for the Advancement of Science, and in the presentation of a scientific paper his extraordinary power of exposition was at once recognized. He was put down for a speech at the great dinner which celebrated the close of the session, and in a letter written on the morning of the day on which it occurred he wrote: "I suppose I shall be compelled to show my Yankee 'gift of the gab.'" He met with a flattering reception at the hands of such men as Darwin, Faraday, Murchison, Sedgwick, Brewster, Mallet and Adams. He writes to his brother: "You may imagine how my heart beat to hear your name so honored and to have our labors so warmly eulogized."

The younger Mallett, who was present on the occasion, afterwards said of it: "Although I was but a boy at the time, attending the meeting with my father, I recollect most distinctly the marked impression made on the large assembly by Professor Rogers's speech and the enthusiasm it kindled. It came late in the evening, after much, perhaps most, of the matters appropriate to the occasion had been utilized by others, yet it was clearly *the* success of the banquet. Americans were less known in England than they have since become, and the slight foreign flavor which accompanied a speech, excellent in itself, and fluently delivered in the mother tongue, added to the piquancy and effect." The orator, like the poet, is hardly a manufactured product, but all who have occasion to lecture on scientific subjects will be greatly interested in and benefited by the many hints as to his own ideas of how difficult subjects may be clearly set forth, which will be found in Professor Rogers's earlier letters to his brothers.

In a letter to his brothers, James and Robert, written from Virginia in 1841, he writes as follows: "Do not attempt to crowd too much into a single lecture, and avoid the common error of experimenting for the eye and not for the understanding. Every experiment ought to be accompanied by a full and clear explanation, and this cannot be too explicit and elementary. Cultivate a deliberate and distinct enunciation without sacrificing earnestness and animation of manner. Above all, do not attempt to be over choice in your phraseology, but use the language suggested at the moment. * * * * In my view, the very first thing to be sought is a feeling of ease and confidence, and this, when the subject is thoroughly understood, you cannot fail to secure at the outset by giving play to some enthusiasm, and, as Rutledge advised, 'speaking right on,' even though at times your phrase may be obscure, inelegant or even incorrect."

The whole of his extensive correspondence with his brothers is filled with evidences of the intense affection and brotherly love which existed among them. They understood and appreciated one another. In 1822 James, aged 20 years, wrote to William, two years his junior: "I have, I think, perceived in Henry (aged 14 years) that constitution of mind which is admirably fitted for success in this world and which, if properly cultivated, would mani-

fest genius of no ordinary cast." Some years later William wrote: "* * * But by and by, my dear Henry, we shall, I trust, be able, shoulder to shoulder, to win a position in which we may enjoy ourselves in science and society, free from all anxiety and in a spirit of entire independence." Again on a Christmas day several years later: "My heart longs more than I can express for the coming time when we may all spend together, as in childhood, these festival days, and when we shall always be so near as not to feel the sense of separation."

Both Henry and William struggled against many difficulties, the former in Pennsylvania and the latter in Virginia, to secure the legislation necessary to the execution of a geological survey, and their experiences, as recounted in their correspondence, may serve to encourage those who are struggling towards similar results in more modern days. In 1841 Henry sent to William the complete verbatim report of the speech of one Senator at Harrisburg, one who in private conference had promised his support, which was as follows: "Mr. Speaker, I shall vote against this appropriation, on the ground of its unfairness to other sciences of like nature to this geology. The bill, sir, makes no provision for phrenology, physiognomy, animal magnetism and the highly important science of *water-smelling;* it is partial and I shall vote against it." Both William and Henry had rare gifts of argumentative power and it was exceedingly uncommon for either to fail in carrying with them men whose support was needed. It was his eloquent earnestness and unselfish enthusiasm that brought to Professor Rogers the greatest success of his life, the establishment of the Massachusetts Institute of Technology.

The first plan for the organization of this institution he drew up early in the year 1846, several years before he left the University of Virginia. In a letter to his brother Henry he says: "Ever since I have known something of the knowledge-seeking spirit and the intellectual capabilities of the community in and around Boston, I have felt persuaded that, of all places in the world, it was the one most certain to derive the highest benefits from a polytechnic institution." When in 1860 he thought the time had come for an active prosecution of his scheme he was tireless in his labors, preparing and submitting plans and reports for the Legislature, delivering public addresses on the importance of technical and scientific training, enlisting support from men of wealth and influence, becoming, in fact, himself the embodiment of the whole enterprise. It is unnecessary to say that the story of the last twenty years of his life is, in a large measure, the history of the first twenty years of the Institute.

The frequent references in his correspondence to the intellectual and scientific activity of the time are extremely interesting. To one accustomed to the quieter and more deliberative methods of the South in all matters of a literary or scholarly sort the intensity of life in Boston was something of a revelation. Henry Rogers was the first to taste of this and he wrote to his brother William as follows:

"For a man of any brains whatever, Boston has no peace or quiet; all is restless excitement and unproductive change of thought and of pursuit. The overworking of the brain here without the fruits of intellectual labor is appalling to a mind of contemplative tendencies. Often do I envy you and Robert your calmer studious atmosphere."

The active dissipation of mental energy thus portrayed may not be entirely absent from the intellectual life of the 'Huf' even to-day, but Professor Rogers was not frightened by its existence forty years ago and he speedily adapted himself

to his changed environment. Although he shortly became a prominent figure in social as well as scholarly circles he still retained his fondness for real, hard scientific work, and during his busiest life in Boston made many scientific investigations of great interest and importance.

His personal acquaintance with eminent men of science on both sides of the Atlantic was extensive and his occasional references to them in his letters add greatly to their value. It was in the earlier years of his connection with the University of Virginia that Professor Sylvester came from England to succeed Bonnycastle as professor of mathematics. Professor Rogers had for some time after the death of the latter carried on the work of the department and he was naturally much interested in the arrival of his relief. He wrote: "For several days we have been anxiously looking for the arrival of Professor Sylvester; we learn he lost all his baggage in Boston; this may have detained him"—which goes to show that some of the personal peculiarities of the distinguished mathematician were not confined in their exhibition to later periods of his life. Again, a few weeks later: "The faculty, students and others attached to the University are all greatly pleased with Mr. Sylvester. He was terribly embarrassed at his first lecture, indeed quite overwhelmed, but has been doing better since. He has a good deal of hesitation, is not fluent, but is very enthusiastic and commands the attention and interest of his class." His brother, Robert E. Rogers, who had for some time filled the chair of chemistry in the University of Virginia, was appointed in 1852 to the professorship of chemistry in the University of Pennsylvania, made vacant by the death of his brother James. He was succeeded in Virginia by Professor J. Lawrence Smith, of Kentucky, already a chemist of distinction. He brought with him two young men as assistants, George J. Brush and Ogden N. Rood, both of whom were to achieve distinction in later years. Of the first Professor Rogers wrote in 1852: "Young Brush is a zealous mineralogist of the Yale School, and seems to be familiar with all parts of chemical analysis. He talks a great deal and very admirably of young Silliman and Dana, and I find that he supposes New Haven to be the great center of American science." In 1853, after having resigned his professorship in the University of Virginia, he wrote concerning the well-known professor of physics in that institution: "My successor is young Mr. Smith, the mathematical tutor, and a favorite pupil of mine."

In 1857 Henry D. Rogers was appointed to a professorship in the University of Glasgow, Scotland, and the correspondence of the brothers became more interesting on account of the wider range of personal acquaintance and association which naturally resulted. In 1859 William wrote to Henry: "I read William Thomson's speech with great interest, and should be glad to see him operate with his ingenious instruments. It is rare to see such profound mathematical knowledge united to such skill in its application to physical questions, and such ingenuity in mechanical contrivance." It would be difficult to find a better description of Lord Kelvin than this. Henry had lectured at the Royal Institution, and on March 11, 1856, William wrote: "Tell me in your next what sort of an audience you had at the Royal Institution. What is Faraday about just now? and Wheatstone? Tyndall seems to be taking a leading part at the Royal Institution. He has fine talents and I hope he is a good fellow; but where is there another Faraday?"

An interesting letter dated August 1, 1860, from James Russell Lowell, who was then editor of the *Atlantic Monthly*, reveals the fact that Professor Rogers had sent him

a list of remarkable blunders in an article on meteorology which that magazine had published. The criticism is accepted in a most good-natured fashion, and Mr. Lowell explains how he proposes to make acknowledgment of the mistakes in the *Monthly*. It is to be done by a humorous editorial, in which the blame for accepting the unfortunate article is to be thrown upon the 'Æsthetic Editor,' who ran the establishment all alone, during the absence of the 'man of science;' and all this, Mr. Lowell says, because "no right-minded magazine can allow itself to be corrected *ab extra*." One might almost conclude that modern journalism had learned some of its lessons from this venerable and always proper and respectable periodical.

A note from Charles Sumner, written at Washington in 1863, reveals something of the anxiety by which men's minds were filled in those days. It concludes: "I wish I could talk with your brother for half a day. Remember me to him most kindly. I know he keeps his loyalty. But what does he say of England—our England—and her shortcomings?"

Indeed there is nothing in these volumes more impressive or more worthy of the distinguished man whose life they unfold than the continued utterances of patriotism and loyalty in which his letters during the war period abound. In giving full weight to this statement it must be remembered that the greater part of Professor Rogers's life was spent in the South; that he grew to maturity amid Southern influences and that he numbered among his personal friends many who were afterwards prominent in the attempt to overthrow the government.

During the early 'fifties' there are frequent references in his letters to the storm which he distinctly saw was threatening the Republic. His faith in the indestructibility of the Union was lasting and strong. In 1856, writing of the difficulties in Kansas, he said: "I am, however, of those who think that our Union is too strongly framed in Constitutional right, and bolted together by mutual interest, to be severed by even such a shock as this." In 1858 he wrote to Henry: "I see with sorrow and indignation that Senator Mason contemplates some general provision for bringing new States into the Union by *pairs*, so as to maintain the present balance between the slave and free States! But this *cannot be done*." Early in 1861, again to Henry: "The fears of State Street and the prejudices of Beacon Street may have some effect, but the great mass of New England and, I think, of the free States in general, will refuse a compromise which claims national protection to slavery far beyond the extent of the present Constitution." And a few days later: "Should the Gulf States remain out of the Union I see little reason to expect a better fate for them than is seen in the degradation, destruction and fickleness of the South American Republics."

During the years in which the Civil War was waged Professor Rogers was especially active, through his brother Henry, in striving to enlighten the people of Great Britain as to the real situation in this country, and there can be no doubt that the excellent social relations which the two brothers enjoyed with people of rank and influence in London, Edinburgh and Glasgow contributed largely to this end. Immediately after the firing upon Fort Sumter William wrote to Henry at great length, saying, among other things: "It is of great importance that the position of the free States and National government in this contest should be truely known in England. Every word of sympathy, or even of toleration, for the South arising from Europe, and especially from England, is magnified by the excited people there and does great harm. * * * It grieves and mortifies me to see several of my old

friends and pupils among the most passionate leaders in this revolt."

Professor Rogers found many channels in which to suppress his feelings of loyalty and patriotism, and the newspapers of the time record the fact that only a week or two after the outbreak of hostilities when he was called upon to speak at the Thursday Club on some matter pertaining to science he "very gracefully declined to discuss the topic proposed, and then made a stirring appeal to the Club in favor of providing a regiment of our brave volunteers with knapsacks." This appeal was seconded by the Hon. Edward Everett, the President of the Club, and in a few minutes a thousand dollars were subscribed.

Innumerable examples showing this intense spirit might be quoted, not alone from letters to his brother in Glasgow, but from those to many prominent Englishmen whose friendship he enjoyed. During the darker days, in spite of his feeble health, he made patriotic addresses on Boston Common and on September 26, 1862, he referred to the Emancipation Proclamation of President Lincoln in the following thrilling words, a part of a letter to his brother Henry: "The great event since my last letter, the greatest event beyond comparison of the war, is the late proclamation of the President, declaring the slaves of all rebellious States after January next to be *forever free*. On the 22d of September this momentous voice was uttered. On that day—in a sublimer sense than ever before—*the sun crossed the line*."

Under date of July 5, 1863, he describes the celebration of the 'Fourth' in Boston. Dr. Holmes gave the oration in the 'great theatre to an audience packed to the dome,' and the enthusiasm was great, all hearts being absorbed in one feeling of patriotism.

As evidence, however, that his interest in the progress of science was by no means dormant during those potentous days, he adds: "What kept me in the city, however, was my interest in the exhibition of the electric light, which the Council, at the instance of George Hale, encouraged by me, decided to make one feature of the evening celebration, as a substitute for part of the usual fireworks." He describes in interesting detail how Ritchie accomplished a superb success by putting a battery of 250 cells on the top of the State House dome, from which a 'flood of light' was thrown upon over 100,000 pedestrians who thronged the streets.

But surely enough has been quoted and enough said to give some notion of the extreme interest of these volumes, not only to scientific men, but to all intelligent people who admire exalted character and lofty sentiment. America has produced no finer type of man than was exhibited in William Barton Rogers, who showed that it was not impossible for one who was primarily devoted to learning and original research in pure science to be at the same time a lovable companion, an eloquent lecturer and a man of affairs whose influence upon his contemporaries resulted in the creation of new institutions and the remodeling of old. It is even now too early to recognize in full measure the value of his life to the people, to whose best interests he showed a rare fidelity.

T. C. MENDENHALL.

---

*THE MERTON RULES.**

THESE are the Code of Nomenclature "at present in force for regulating all work done in the study of Microlepidoptera at Merton," and "the object of these rules is to insure absolute obedience to the Law of Priority." In so far as this Code is pecu-

* Rules for regulating Nomenclature with a view to secure a strict application of the Law of Priority in Entomological work. Compiled by Lord Walsingham an [and] John Hartley Durrant. Longmans, Green & Co.: London, New York and Bombay. 2 Nov., 1896. 8vo, pp. 18.

liarly or exclusively adapted to the exigencies of entomological work it is of course not within the purview of ornithology; but its most avowed object of insisting upon the Law of Priority, its whole tenor, and most of its fifty-one canons, are no more pertinent to one branch of zoology than to any other. Lord Walsingham and his secretary thus submit a set of rules to the consideration of all zoologists, and no apology is needed for examining them with special reference to the A. O. U. Code.

Naturalists are in substantial agreement upon such a large majority of the propositions which bear upon the 'highly-contentious' subject of Nomenclature that we should expect any code drawn up by competent workers to be good in the main. Such is emphatically the case in the present instance. If, therefore, we seem to dwell upon the exceptions we take, to an extent disproportionate with the commendation we give, it will be understood that the latter goes without saying. Probably four-fifths of these rules will receive general unqualified assent; it is mainly regarding the remainder that we have here to do. Most of these may be reasonably questioned, and some of them are likely to be regarded as highly objectionable.

We think that the authors make a strong point in the introduction, but it is made so quietly that its full force may not be recognized at first sight. This is where (p. 4), referring to other codes, the authors say they "are not aware that in any of these rules the actual work and intention of an author has been guarded to the same extent as the names which he has given to his conceptions," and then add: "It has been one of our objects to define a method by which the recognition of antecedent work can be consistently secured, regarding this also as no less a moral obligation capable of being met by the same rules which apply to mere names."

This raises a large question, concerning which we are heartily on the side of the authors. We have too often heard it said that, as we cannot enter into the inner consciousness of another, especially if he have lived in other times and been long dead, we have no concern with his spirit, purpose or intents, but only with his acts, and that consequently we must go by what he actually did, without regard to what we may think he intended to do. We believe this to be bad—unjust and dangerous; Lord Walsingham has the right of it in introducing something of a moral or ethical principle, difficult as such may be of application in all cases. An author's intent or purpose can generally be fairly presumed or inferred from his writings; when such presumption or inference is reasonable it surely should not be disregarded, and the cases must be very few in which no meaning is discoverable.

Example: In founding his genus *Dendragapus* Mr. Elliot intended to separate grouse of the *obscurus* group from those of the *canadensis* type. That was the sole intent, purpose, scope and function of his generic name. What right, then, has any subsequent author to use *Dendragapus* for the sole purpose of uniting *obscurus* with *canadensis?* None; such a travesty of the generic name, such a perversion, or rather reversal, of Mr. Elliot's express purpose, is simply nomenclatural hocus-pocus, and as such it is puerile, unscientific and immoral.

There is another point in Lord Walsingham's introduction we must pause to applaud heartily. Though it be one of those which, as we say above, go without saying, it is particularly well said (p. 5): "The object of all rules should surely be to secure precision, uniformity, and finality: any sacrifice of these objects to considerations of mere convenience can only result in the creation of greater inconvenience at some future date. The inconveniences from which

workers in entomology now suffer would have been entirely avoided had the earlier authors studied and recognized the work of their predecessors, or adopted some such rules as are here set forth, beginning from the time of Linnæus. The earliest sinner in this respect was Fabricius, but Stephens in creating the necessity for Rule 48, has exhibited even greater ingenuity in his aberrations." Here, again, is an obvious ethical principle. We do owe something to posterity, notwithstanding the question which some wit once asked: "What has posterity done for us?" This debt is in the nature of a moral obligation not to consult our own present convenience at the expense of those who are to come after us. And if we may disregard the altruism involved, then self-respect and an enlightened selfishness should alike prompt us to the same end, merely as a matter of looking out for our own good repute.

A part of Lord Walsingham's 'Premiss' will be hailed with acclamation by almost every American zoologist. It is as follows:

"Zoology became an intelligent science when it was recognized that every species should possess a special name and every genus a generic name. This system of nomenclature was first enunciated by Linnæus in the 'Systema Naturæ' (edition X.), 1758; and as we owe the conception of the special and generic name to Linnæus, we are bound to commence our nomenclature from the year 1758, when he published his epoch-marking work."

Shade of Strickland! Requiescat in pace! We do not propose to echo an anthem to this requiem, nor even to argue the point; for we could say nothing that has not been said fully and perfectly well in the A. O. U. Code itself in support of this reasonable proposition—one of self-evident logical necessity; and if what is recorded there does not budge our British friends, nothing will move them from the isolation of their insularity. We know that most of our respected colleagues on the other side of the herring pond still stand on the rock of offense, whence to denounce with objurgation those who do not subscribe to the B. A. Code. Possibly we undertook to split that rock with the butt end of our wedge; probably Lord Walsingham may prove to have insinuated the thin edge from his own coign of vantage. He may not be the first among English naturalists to favor the heresy of 'Linnæus at '58;' but he is certainly one of the strongest, and much may be confidently anticipated from the force of his example. We remember once discussing with him in person the 'American idea' of Trinomials. We may have been persuasive, though we failed to be conclusive, in our presentation of that case to his liberal and progressive judgment; but the stand he has now taken against the extreme conservatism of his countrymen leads us to the confident hope of his enlightenment even upon those 'dark sayings' of Trinomialism. If the scales could fall from the eyes of such a one as Saul of Tarsus, a Paul of London, Cambridge or Merton may not be a zoological impossibility in the course of natural evolution.

Passing by most of the Merton rules as self-evident, or as admitted by the concensus of naturalists, or else as peculiar to microlepidopterists*, we note some few

* A valued entomological friend of high standing, who has not authorized the use of his name in this connection, writes to us regarding some of these: "I think that most entomologists would take exception to the group of rules beginning with No. 19 and ending with No. 25, except that No. 23, since it begins with the words 'it is advisable,' is acceptable. Similarly, under No. 33, *e. g.*, Zeller's correction is not admissible. Under No. 38, the third paragraph, indicating that the type is the sum of the co-types. Mr. Oldfield Thomas's terms under No. 39 have not come into general use, though they are sensible enough. Under No. 41: No one accepts the idea that the type of the genus is the sum of the species as under 2 and 3."

others for special approval or the reverse.

Rule 18. "If it be held that the generic and special names may not be tautonymic, the law of priority will determine whether the special or the generic name should be changed, *e. g.*, *Cossus cossus*, L." The proviso in this case nullifies the rule for us, because we do not forbid tautonymity. Our practice is bad—obviously so, on the score of literary propriety; it is to be strongly discouraged; but it seems an unabatable nuisance, which most naturalists will put up with perforce, and it has one redeeming feature—we know absolutely what every tautonym means.

Rule 19, bringing up 'three classes' of invalid names, is likely to remain a bone of contention in one-third of its scope. We all agree regarding homonymous names, that they are absolutely to be rejected; so, of course, regarding synonymous names. But not so regarding homophonous words, for surely no one of us would reject *Seiurus* because its sound when spoken is identical with that of *Sciurus*.

Rules 20 and 21, hanging on the foregoing, are open to difference of good sound opinion, possibly because, for one reason, it may not be always clear what words come under these provisions. It is desirable, but probably impossible, to have rigid rules here. No rule can possibly be more rigid or stable than the sum of the cases to which it applies; but the cases intended to be covered by Rules 20 and 21 are so shifty and mobile that no seive can be devised with meshes fine enough to catch them all. We confess ourselves puzzled here; we cannot offer better rules than Lord Walsingham has, yet we doubt their sufficiency. It seems to be a case where common sense, tact and expertness may work better than any formality. Let us agree, as most, if not all, ornithologists would, that *Telea* invalidates *Teleia*, and *Pandemos* invalidates *Pandemis;* does *Ucetia* invalidate *Eusesia?* Personally, we should say that would depend upon the etymology in the case. If *Ucetia* be merely a bad way of spelling *Eusesia*, the etymon in the two cases being identical, we should say they were the same word, not available for two names, for all that they happen to be spelled so differently. We would, therefore, spell to the best of our ability both names as one, and use the right spelling or not according to the provisions of some other rule regarding homonyms. But if *Ucetia* and *Eusesia* be of different etymons, only accidentally homophonous, we should regard them as distinct words, neither of which would invalidate the other. Yet we know that others might take exactly the opposite view and argue strongly in its favor. As we said in substance, this whole class of cases has thus far proven refractory to, or elusive of, any rule naturalists have had the wit or ingenuity to devise.

Rule 22. "A name wrongly written is invalid if, on legitimate correction, it becomes homonymous or homophonous with a valid name; *e. g.*, *Grapholitha*, Hb., invalidates *Grapholita*, Tr." The A. O. U. Code would have simply to quash this rule, because it forbids all correction of names, 'legitimate' or illegitimate. We think it is the very worst blot on our Code, which has done more to bring that work into disrepute than all our other weak or bad points put together. It puts a premium on ignorance or carelessness to rule, as we do in Canon XL., that a name shall endure exactly as it originally appeared in print, no matter how mangled it was, unless a *typographical* error be evident. Why be so fierce with the poor compositor, and let the guilty author go scot free? We need not become formal impurists for fear of purism. Personally, we decline to bind ourselves to misspelt words forever, for no better reason than that some zoologists, too ignorant or

too slovenly to spell them properly, sinned in the beginning. We are opposed to 'original sin,' whether as a theological dogma or a canon of nomenclature. On this subject we cite from a private letter lately addressed to us by one of the most learned and distinguished of American philologists, Professor C. P. G. Scott:

"I think you are quite right, as a scholar, in your disapproval of the mechanical rule which, as a member of a committee constrained to compromise, you passively sanctioned in 1886. It seems to me that these verbal uncertainties will *never* end, no matter what committees may recommend or do. Therefore, since the only purpose of compromise is to end uncertainties and discrepancies, it would be better for your committee to revise the code of nomenclature with reference to etymologic principles which *can* be ascertained and stated, and to consider all material deviations, intended or unintended, old or new, as if misprints to be corrected in subsequeut works. Etymologic principles are a good deal more stable and visible than is commonly supposed; but you know by long observation that not every zoologist (particularly in France) is sound in his tackling of Greek and Latin."

Our zeal for 'spelling reform' might not now lead us to the length it did, for example, when we emended Richardson's genus *Aplodontia* into *Haplodon*, only to find, to our dismay, that in its new guise the name was homonymous with several others of prior date, and therefore inadmissible for the genus of mammals. We would treat such a case as incorrigible, and let it go at that, without regard to its etymology. It seems to us that tact, discretion and common sense, applied to each individual case, is likely to work better than any rigid rule which could be devised to cover all cases. We are not such rigid purists as to sacrifice the Law of Priority to purism. In fact, we would not go to the length Lord Walsingham does in '33 *e. g.* (2),' where he 'corrects' *cretidactylus* into *gypsodactylus*. If both these names mean 'chalk-toe,' as we suppose, the substitution of gypsum for chalk, to prevent a Græco-Latin hybrid, seems hardly required. That is mere purism, only less unobjectionable than the systematic impurism which the A. O. U. Code would force upon us. A certain 'sweet reasonableness' would seem to be the best prophylactic or preventive—better than extreme measures either way. Such heroic treatment is likely to become the mock heroism of opera bouffe. As Horace said, some years ago:

> "Est modus in rebus; sunt certi denique fines,
> Ultra citraque nequit consistere rectum;"

and as Professor B. G. Wilder lately remarked, in the course of his controversy with Wilhelm His:

"As with biologic generalizations, there are few philological rules without exceptions. Yet the reformer, especially if young and enthusiastic, either ignorant of history or undismayed thereby, 'too often imagines that a principle, if right, cannot be carried too far.'" (Barclay, 1803.)

Our A. O. U. committee may be neither very young nor over-enthusiastic; yet this is precisely what we have done to the excellent principle of priority—carried it too far, in attempting to impose verbal abortions upon nomenclature. The results sometimes better befit the nursery in their puerility than the halls of science. Take that miserable botch of a word *Leptotila* Swainson for a genus of pigeons. If the celebrated quinarian had printed *Leptoptila*, in proper form, his genus would have been invalidated by the prior *Leptoptilos* or *Leptoptilus* for a genus of storks, because by our rules a difference of termination in words etymologically identical does not prevent homonymity; but because Swainson or his printer did not mind his *p*'s—whatever he

may have done with his *q*'s—*Leptotila* becomes valid and tenable!* This is mere juggling with the letters of the alphabet; it is absurd, undignified, infantile. We should say, first spell *Leptoptila* correctly, according to its obvious formation, and then decide on other grounds whether or not it be in this form different enough from *Leptoptilus* or *Leptoptilos*. Literary abortion should not be viable in the language of science.

Rule 23 allows difference in termination of words to make formal difference in names, *e. g.*, *Sciaphilus* in Coleoptera and *Sciaphila* in Lepidoptera, on the ground that no confusion results. How it would be did these two fall in the same order of insects is not stated. We believe the practice of entomologists has generally been to allow even identical names to coexist in different orders, on the same ground. Probably the latter state of the case is inadmissible in any other branch of zoology; but on the question whether difference of termination or inflection, as indicating grammatical gender, shall suffice to distinguish names, much might be said either way. Our practice is against it. Yet there stand our *Picus* and *Pica*, and we may yet have to reconsider our present canon on this question. Certainly *Leptoptila* and *Leptoptilus* are better distinguished from each other than *Leptotila* would be from *Leptoptila*. One is a distinction with a real difference, viz., of gender; the other is a distinction with a bogus, spurious, bastard, abortive, illegitimate apology for a difference.

Rule 24. "A name which involves a false proposition is invalid and may be changed." One would think this a self-evident proposition in science—a truism, to adult minds, hardly requiring statutory provision. The reverse would be, or should be, unthinkable in science. Yet so far afield in following the *ignis fatuus* of verbal veneration for the fetish of 'priority' have some of our codifiers been led that they would not dare to correct an error of scientific fact for fear of disturbing the cerements of verbiage in which it was embalmed! Let some one describe an albino crow as *Corvus albus*; shall we go on calling black white to the end of the chapter? Let some one describe a broken-billed popinjay as *Picus semirostris*; shall *semirostris* be the name of any species which has a whole beak? Let Gmelin describe a Mexican woodpecker as *Picus cafer*; shall we declare every time we write the name that it is a South African bird? Yet the last is exactly what we do in the A. O. U. Check List, where *Colaptes cafer* stands in a catalogue of North American birds. It is *brutum fulmen* for us to declare that a name has no necessary meaning. Such declarations simply beat the air in a futile and fatuous manner. '*Cafer*' has no meaning for those who do not know what it means, but those who do know what it means can no more divest it of its reference to a South African locality than they can take away from *Colaptes* its implication of carpentering. Granted that we have plenty of nonsense-words in science—mere combinations of letters, *sensu carentes*; granted that we have to put up with them, and that they do very well, like Smith or Jones; that does not make *cafer* mean Mexican, or *albus* mean black. The proposition is false, in form and in fact; and falsity is foreign to science. Any attempt to save the Law of Priority at such hazard, or im-

* We are sorry to observe that the A. O. U. is not consistent with itself, even in wrong-doing. Thus: (1) *Leptotila* is held to be tenable, from lack of the *p*. Had it been *Leptoptila* it would have been untenable, from similarity to *Leptoptilos*. (2) *Fregetta* Bp. is held to be untenable, owing to a prior *Fregata* of Brisson, and *Cymodroma* is used instead. (3) But *Fregetta* is quite as different from *Fregata* as either *Leptotila* or *Leptoptila* is from either *Leptoptilus* or *Leptoptilos*; *i. e.*, there is no real difference in either case. The A. O. U. is wrong in one of these cases, necessarily—which one?

pose uniformity of nomenclature by the arbitrary authority of an individual or a committee who should go to such a length as to say either that words have no meaning or that we shall use words in wrong senses must fail, for the simple reason that common sense will not be coerced, and sensible writers will go on writing as sensibly as they know how.*

Rule 25 provides for expunging from nomenclature any name which is 'offensive (whether politically, morally, or by its irreverence).' This raises a question of great and probably insuperable difficulty; for we may at once ask, offensive to whom? In a certain sense, science is non-political, non-moral (a different thing from being immoral, of course), and non-reverent of anything but ascertained or ascertainable truth. In religion it is agnostic; in printed decencies it is usually found to side with decent people; in political lampooning it might display partisanship as a part of human nature, without great offence to propriety. It would seem to be a case which ordinary self-respect and regard for public opinion would suffice to regulate; yet we can hardly arbitrate it in its nomenclatural aspects. *Sivatherium* might be as offensive to a Hindu devotee of the cult whose god is invoked in the name of a fossil beast as any other blasphemy. Neither *Phallusia* nor *Ithyphallus* offends more than the translations of these terms would in a medical treatise, nor does *Clitoria* keep a manual of botany out of schools. While the drift and purport of Rule 25 are obvious and admirable, its enforcement to the extent of expunging any names but those quite outside the pale of public decency is probably impracticable. The way to deal with such things is to cut the perpetrator the first time he shows himself in society.

*Dr. B. G. Wilder states, Journ. Comp. Neurology, vi., Dec., 1896, pub. Feb., 1897, p. 334: "No such attempt is known to me." Then he never knew the A. O. U. Code and Check List, which are an attempt to secure uniformity of nomenclature by the authority of a committee, "*quorum pars magna fui.*" But his criticism is excellent: "The very notion savors of ecclesiasticism rather than of science. At the most, individuals have set certain fashions, more or less commendable and permanent, while committees have made recommendations which even their own members may disregard when their information is increased or their views are modified."

We have already protracted this review beyond usual limits, and must hasten to cloture. Several following rules bear upon correction of names, orthographically or zoologically. In the former regard they will be nugatory with those who hold to our Canon XL.; in the latter respect they will command the assent of some naturalists, but not of all. Rule 42 will, we imagine, be found decidedly objectionable, as will most of its corollaries; though some of the refinements regarding types may be specially serviceable in microlepidoptera, while less so or not so in zoology at large. In any event, Walsingham and Durrant have given us in this Code a notable contribution to the literature of the subject, which can be studied to advantage by every zoologist, perhaps by every botanist also. For ourselves, we are among a large number of naturalists who are fully convinced that the A. O. U. Code is, on the whole, by far the best one ever formulated. Our appreciation of its manifold good qualities and general utility leads us not unnaturally to set it up as a standard of excellence with which other codes are to be compared. That we are not blind to its defects is obvious from what has preceded; but it is our very conviction of its strength and worth which makes us feel free to express ourselves perhaps more forcibly regarding its blemishes than we should if we considered it a weak or tender thing that needed nursing. At the same time it were idle to consider our Code a faultless finality; no sensible man is going to be bound by it against his own convictions, and if naturalists are ever to be

blessed with such a thing as an infallible rule of faith and morals in matters of nomenclature that state of beatitude may be sought along the line of one of Lord Walsingham's suggestions: "All branches of zoological study should undoubtedly be represented on any committee entrusted with the task of drawing up rules for general guidance." Pending any final consummation, British ornithologists will no doubt continue to lean upon Strickland and the B. A. Code. American ornithologists, and most zoologists of this country, will stand by the A. O. U. Code; while doubtless the Merton Rules will be respected by most of those entomologists whose requirements are so ably met in this instance.

Elliott Coues.

As said above, the 'Merton Rules' agree in the main, or at least on most points of leading importance, with other recently promulgated Codes of Nomenclature; but they embrace many provisions, by no means all new, which are open to strenuous objection, on the ground that they seriously militate against the stability of names in zoology. Some of these have been pointed out in the foregoing review; others have been passed over leniently or quite unnoticed. On the other hand, some which we consider utterly objectionable have received approval.

Rule 5, for example, provides that "The same name may be used once only in the same grade, with the exception of special [specific] names, so long as they occur in different genera, and of subspecial [subspecific] names so long as they are subservient to different species." Since 'subspecial,' or subspecific, names are often applied to forms of uncertain status, and may be regarded either as species or subspecies by different writers, it is obvious that they should fall under the same rule as 'special,' or specific, names. Otherwise they are open to instability, according to whether the forms to which they may be applied may be regarded as 'species' or 'subspecies' by different authors.

Rule 19 divides 'invalid names, considered merely as words,' into three classes: (1) *Homonymous*, (2) *Homophonous*, and (3) *Synonymous*. 'Homophonous' words are 'words differently written, but indistinguishable in sound, applied to different conceptions.'

Rule 20 provides that "A name homophonous with a valid name is invalid, in accordance with the rule governing homonomy (Rule 5)." (See Rule 5, as quoted above.) This we regard as a pernicious in-innovation. Previous codes advise that in selecting new (especially generic) names those closely resembling previous names in orthography or sound be avoided; but this is the first instance, we believe, where they have been declared invalid. The objections to this rule are: (1) that scientific nomenclature belongs properly to written language, not to spoken language; (2) that whether a name is or is not too near in sound, when properly pronounced, to another earlier name must be largely a matter of opinion, respecting which authors must frequently disagree; this disagreement being necessarily a fruitful source of instability in names. It opens a loophole for the displacement of well-known names by new ones on the ground of personal opinion or preference, perhaps biased by the opportunities thus presented. In all languages there are almost innumerable homophonous words of radically different origin and meaning; why should they not be admissible in the language of science?

Rule 20 is thus in opposition to the intent of nearly all modern codes, which are designed to leave as little as possible open to the notoriously unsafe decision of personal judgment or option in matters of nomenclature.

According to Rule 21, which is an amplification of Rule 20, a name may be only 'so similar to a valid one as to be *almost homophonous*' to be rejected, which, of course, but emphasizes the objections already made to Rule 20.

It follows that Rule 22 is also objectionable (1) in that it provides that "a name wrongly written is invalid if, on legitimate correction, it becomes (either) homonymous or homophonous with a valid name;" and (2) in that it implies the right of emendation of names.

Yet Rule 23 permits, in the case of genera, the use of names which differ merely in 'a different sexual suffix,' as in cases like *Sciaphilus* and *Sciaphila*, in opposition to previous codes and the consensus of probably nine-tenths of present zoological writers. The case of *Picus* and *Pica* is obviously not parallel, inasmuch as these names have come down to us from pre-Linnæan classical writers, who employed them, not interchangeably, but as names for entirely distinct objects. The etymology of these words is admittedly unknown, but their use for centuries as distinct names, applied to totally unlike birds, seems sufficient reason for their use in modern systematic nomenclature, and for their adoption as distinct words, despite the accident of their similarity.*

Rule 24. "A name which involves a false proposition is invalid and may be changed." Note first the use of 'may' instead of *must*, leaving the enforcement of the rule optional, and thus opening a way to instability of names through mere personal opinion or preference. Note, secondly, that it opens the way to wholesale changes on trivial grounds. If a species of a certain genus has been named *minimus* or *major*, and a species is subsequently found that is smaller or larger, the names in question 'involve a false proposition.' And so in cases where names relate to color, as where a species is named *nigra*, or *purpurea* or *rubra*, and is not of the color implied; or in the case of species given geographical names that do not occur in the countries whose names they bear, or in other cases indicate portions of their range which are not characteristic of their distribution. For instance, a Mexican species may have been named *brasiliensis*, or a Peruvian species *cayennensis*, which do not occur respectively in Brazil or Cayenne. This class of cases, as everyone knows, is legion. To avoid the adoption of a rule necessitating such sweeping subversion of names we can well afford to endure the isolated case of a name like *cafer* for a North American woodpecker! *Ludovicianus*, as applied to one of our tanagers, now 'involves a false proposition,' since the species does not occur in Louisiana. There is, in fact, every shade of falseness in names, from a time-honored *Paradisea apoda* to such as involve a falsity so slight as to be of questionable importance in the mind of even the greatest stickler for nomenclatural veracity.

Rule 27 is the corollary of the principle laid down in the 'introduction' regarding the 'guarding' of the 'actual work and *intention* of an author,' quoted, and so emphatically commended in the foregoing review of the 'Merton Rules.' The Rule is: "The right of an author to correct antecedent work is undoubted, provided always that in making such corrections the *intentions* of his predecessors be respected, unless proved to be erroneous." This is an innovation fraught with the gravest possibilities for mischief. Heretofore it has been deemed to be the only safe course to take an author's work as he left it, without attempting to

*Since this was written this point has been touched upon in this journal (SCIENCE, N. S., Vol. V, No. 126, May 28, 1897, p. 847) by Dr. Stejneger, who says *Picus* and *Pica* "are distinct and separate Latin classical names for widely different birds, though the philological root of the two words is probably the same."

guess at what he intended to do, even if in rare cases we may be compelled to ignore an obvious intent. The trouble here is that when the bars are let down there is no limit to the license authors may take, for one reason or another. The case of *Dendragapus*, cited above as an illustration, shows to what strange conclusions such license may lead. It is purely a matter of opinion whether *obscurus* and *canadensis* are generically separable. For those who think they are not, the only course open is to treat them as members of one genus, and to take the oldest tenable name available for the group, in accordance with a fixed principle of nomenclature especially provided for such emergencies. The first tenable name happens in this case to be *Dendragapus*. If this is 'puerile, unscientific and immoral,' there is no help for it, even under the 'Merton Rules.' All it amounts to is a difference of opinion between ornithologists as to the value of the differences which distinguish the two species *obscurus* and *canadensis*.

Rule 30 provides, among other things, that "an orthographical correction may be made by emending a name wrongly formed." This is not an innovation, as the same provision is found in other codes. But it is diametrically opposed to Canon XL. of the A. O. U. Code, which provides that "the original orthography of a name must be rigidly preserved, unless a typographical error is evident." Sound and weighty reasons are given in the A. O. U. Code for its adoption ; it is in accord with the practice and advice of many eminent authorities—some of whom lived before the A. O. U. Code was thought of, and were scholars as well as naturalists; and, while still repellant to some, it is obviously gaining ground, as there is an increasing number of writers who consider fixity of names as of higher importance than the correction of grammatical or philological imperfections in their construction. Not only is this view shared very generally by American mammalogists, but we have recently found that it has strenuous advocates among eminent specialists in other departments of zoology, notably in entomology.

When we consider that purists and classicists are often at loggerheads among themselves over the emendation of a name; that names are often 'emended' out of all resemblance to their original form and become, to all intents and purposes, new words; that, when less modified, the initial letter is often the part affected, and that through this change the name takes a new place in all indexes and in all alphabetic lists where it appears, resulting in an inconvenience of serious magnitude—it seems far the lesser of two evils to put up with here and there an orthographic abomination than to sacrifice stability of nomenclature to philological refinement. Carelessness or ignorance in the construction of names is to be deprecated and frowned upon, as it is in the remarks under the much abused Canon XL. of the A. O. U. Code, which, therefore, does not place 'a premium on ignorance or carelessness,' but simply chooses by far the lesser of two evils. It conforms to the whole spirit of the Code, which aims at stability in names, and the elimination of every element of instability that may arise from personal preferences in matters where opinions must inevitably differ to a greater or less extent. Even my fellow critic of the Merton Rules cannot agree with Lord Walsingham as to the extent emendation is allowable, as in the above-cited case of changing *cretidactylus* to *gypsodatylus*.

As to the case of *Leptotila*, dwelt on at length above, if 'tales out of school' were admissible, the inside history of its adoption by the committee would afford an amusing commentary on some of the remarks above made. Suffice it to say that

as *Leptotila* was repeatedly used by Swainson, and thus with obvious intent, it could not be ruled out as an 'evident typograhical error' for *Leptoptila*, and so was accepted as simply a name, and therefore available under the A. O. U. maxim, "A name is only a name and has no necessary meaning;" or, to cite the B. A. Code of 1842, "In truth, it matters not in the least by what conventional sound we agree to designate an individual object, provided the sign to be employed be stamped with such an authority as will suffice to make it pass current." It is, therefore, entirely thrown out of the category of such cases as *Fregetta* and *Fregata*, discussed above.

It certainly is to be hoped that all sensible writers will go on writing as 'sensibly as they know how;' but in the above remarks on *cafer* and *Leptotila*—ostensibly anent the 'Merton Rules,' but really in ridicule of the A. O. U. Code—it is evident that not all of the 'puerility' is on the side of the supporters of Canon XL.

Nos. 34–37 of the Merton Rules call for no comment, being in essential conformity to current usage. We must dissent, however, from Rule 38 in so far as it relates to 'co-types,' this part being to the effect that when a species is 'described from more than one specimen, no single one being selected as the type,' the 'type' in this case is 'the sum of the co-types.' The position here taken seems so obviously unwarranted as to hardly merit discussion.

Rules 42–48, on the restriction of genera, are refinements of existing rules relating to this subject, treating the matter in detail on lines already for the most part generally approved.

Rule 49 provides a most cumbersome way of designating subspecies. Rules 50 and 51 relate respectively to the use of signs and methods of citation, the latter formulating practices already more or less in vogue.

As already said, the 'Merton Rules' are in the main in accord with other advanced modern rules and usages; the innovations, as noted above, are for the most part positively mischievous, from the standpoint of fixity in names; the adoption of the tenth edition of Linnæus's 'Systema Naturæ' we regard as the one especially commendable feature of this new code, only so, however, on account of its geographical origin, since all recently promulgated Codes take this date as the starting point for the law of priority.

J. A. ALLEN.

THE ORIGIN OF GREEN RIVER.

IN his Current Notes on Physiography in No. 121 (April 23d) of this JOURNAL, Professor Davis, under the heading: 'Is Green River antecedent to the Uinta Mountains?' remarks that this question is not closed, as had been assumed by Mr. J. D. Irving in his paper on 'the Brown's Park beds of Utah,' and further that it does not appear clear from the latter's statements whether he considers it to be a superposed river, as maintained by me, or antecedent, as stated by Powell. He very pertinently remarks that it is remarkable, considering how frequently the Green is referred to as an antecedent river, that so little attention is given to the difficulties that such origin involves. Long before the appearance of the two textbooks he quotes (Tarr and Scott), LeConte and Geikie had each referred to it as antecedent and illustrating the slow uplift of mountain ranges, in apparent unconsciousness that any other view is possible. Suess, on the other hand, in his exceedingly careful review (Antlitz der Erde, I., p. 736) of the structure of this region, adopted my view without any reference to that of Powell.

In Powell's original publication (Exploration of the Colorado river of the West, p. 153) he makes no mention of the struc-

tural difficulties the river might have to contend with, but contents himself with the simple statement: "The river had the right of way; in other words, it was running ere the mountains were formed; not before the rocks of which the mountains are composed were deposited, but before the formations were folded so as to make a mountain range." Later he remarks: "I reserve the subject for a more full discussion in my report on the geology of the Uinta mountains." In this report, however, I had been able to find no mention of the subject whatever, and I had assumed that upon further study he had found the difficulties in the way of his theory too great to be explained away.

My study of the region was made in the summer of 1871. Powell continued his during the years 1874 and 1875, after, at his request, I had explained to him my views as to the structure of the range.

Upon the following facts with regard to its geology we are both agreed. The uplift of the Uinta Arch commenced at the close of the Cretaceous. During Tertiary times there were deposited in the lakes, which washed either flank of the range, not less than 8,000 feet of sediments that were derived, in part, at least, from the degradation of that Arch.

Now, as my map shows, these Tertiary beds, overlapping in a nearly horizontal position the upturned and truncated edges of the various formations composing the original arch, reach altitudes of 9,000 and 10,000 feet at various points along either flank of the western and higher portion of the range. The eastern portion of the range, through which the peculiarly winding cañons of the Green River have been cut, has an elevation of only 7,500 to 8,500 feet, a few of the higher points reaching 9,000 feet, and in one case 9,297 feet.

According to Powell's theory, however, the river had determined its course before the uplift of the arch, and has continued to occupy the same bed to the present day. "The principal cañons through the mountains," he says, "had been carved nearly to their present depth before the last of these sediments were deposited."

What, then, became of the river while these 8,000 feet of Tertiary sediments were being deposited? It could hardly have continued its course at the bottom of the Tertiary lakes while the sediments were depositing. But if it ceased to flow during this time its bed must have been filled with sediments as well as the rest of the country, and when the lakes were finally drained, it is hardly conceivable that, in redetermining its course across the 150 miles of Tertiary beds on the north side of the range, it should have attacked the flanks of the Uinta range, themselves partially buried, at exactly the same point it had entered before.

There are many other features that require explanation before Powell's hypothesis can be accepted, one of which Professor Davis has pointed out in the Brown's Park depression, a longitudinal valley 40 miles long and 5 to 6 miles wide, open only at its eastern end, and nearly in the axis of the range. It is supposed to have been formed by engulfment, and has twice been occupied by Tertiary waters, once in Eocene, and once in Miocene or later times.

How the river kept its course (which three times wantonly leaves the open valley to cut cañons in its hard walls) through all these vicisitudes, would seem to require a more direct explanation than that "The river preserved its level, but the mountains were lifted up, as the saw revolves on a fixed pivot, while the log through which it cuts is moved along."

Inasmuch as the promised discussion did not appear, I have recently asked Major Powell to explain to me his conception ot how these things could have been accom-

plished, but he says it is so long ago he no longer remembers the course of reasoning he followed at the time.

I assume that Capt. C. E. Dutton, who at Powell's request took up and completed the latter's Colorado cañon geology, is likely to have voiced his matured opinion on this point. In his paper on the Grand Cañon (2d Ann. Rep. Director U. S. Geol. Survey, p. 62), in treating of the persistence of rivers, Dutton gives a most graphic description of the course of the Green river in its passage through the Uinta mountains. In spite of the fact that he places Horseshoe Cañon on the south instead of on the north flank of the mountains, it is evident that he must have read Powell's description, for he uses not only his metaphor about the 'right of way,' but also the simile of the saw preserving its position while the log moves. Whether consciously or not, however, he certainly does not agree with Powell's hypothesis, for he says in conclusion: "What then did determine the situations of the present drainage channels? The answer is that they were determined by the configuration of the surface existing at or very soon after the epoch of emergence. Then, surely, the water courses ran in conformity with the surface of the uppermost (Tertiary) stratum."

Dutton elsewhere states more definitely that the course of the Green or Colorado river south of the Uinta mountains was determined at the close of the Eocene. If this is correct, I was probably wrong in assuming that the Green river first found its way across the Uinta mountains after the Wyoming (Bishop's Mt.) conglomerate had been deposited, because I found undisturbed remnants of this formation on either side of the river, both on the north and south flanks of the mountains and at such elevations that, if the beds were continued across the intermediate country on the same level, they would completely cover that portion of the mountains through which the Green river now runs. I have for a long time been hoping and still hope that some other geologist may make a more thorough examination than I was able to at that time, and determine the nature and extent of this singular formation, which has never been satisfactorily accounted for. Whatever may be the outcome of such an examination, it would seem proper that the antecedent origin of this river should be held in abeyance until some positive evidence of it can be furnished.

S. F. EMMONS.

U. S. GEOLOGICAL SURVEY.

ZOOLOGICAL NOTES.

THE SCIENTIFIC NAME OF THE VISCACHA.

ONE of the best known mammals of the pampas of the Argentine Republic is the viscacha, now usually called *Lagostomus trichodactylus.* Unfortunately this name proves to be untenable, but in order to show that such is the case it will be necessary to refer briefly to the history of the species. The animal was first described in 1801, by Azara, who considered it identical with *Cavia acuschy* of Gmelin, which is now known to be an entirely distinct species. Rafinesque, in 1815,* proposed the genus *Viscacia,* apparently without description, so that his name is not entitled to recognition. One year previous, in 1814, according to Waterhouse (Nat. Hist. Mamm., Rodentia, 1848, p. 213), a living viscacha was placed on exhibition in London,† where it was examined by Blainville and Cuvier. Blainville soon after described the species as *Dipus maximus.*‡ Some years later the same animal came into the possession of Brookes, a member of the Linnæan Society of London, who gave a full description both of its

* Analyse de la Nature, 1815, p. 56.

† Burmeister states that there were two.

‡ Nouv. Dict. d'Hist. Nat., nouv. éd., XIII., 1817, pp. 117–119.

skeleton and of its external characters in a paper read before the Society on June 3 and 17, 1828.* Brookes recognized the fact that the viscacha belonged to a distinct genus which he named *Lagostomus.* He also changed Blainville's specific name *maximus* to *trichodactylus* on the ground that it became inappropriate in connection with a genus represented by only one species. Authors who have adopted *Lagostomus trichodactylus* have reduced *Dipus maximus* and other subsequent names to synonymy, but, almost without exception, have overlooked one of the most important references to the species.

In 1824 Schinz began the publication of his 'Naturgeschichte und Abbildungen der Saugethiere,' and on page 244 of this work gave a full description of the viscacha, calling it *Vizcacia pamparum.* A comparison of the title pages of this work (1824) and of volume XVI. of the Transactions of the Linnæan Society (1828) seems to indicate that *Vizcacia pamparum* Schinz has 4 years priority over *Lagostomus trichodactylus* Brookes. Although Schinz's name was undoubtedly published first, its actual date of publication is uncertain. Schinz's Naturgeschichte appeared in 29 Hefte, at intervals from 1824 to 1828, and, as the description of the viscacha is inserted near the middle of the book, it was probably not published before 1825 or 1826. I have been unable thus far to ascertain the dates of publication of the separate parts of the Naturgeschichte, but in the copy examined is a notice to subscribers, printed for distribution with the 29th Heft, and dated February 28, 1828, stating that this is the concluding part of the volume. Schinz's work was evidently completed several months before Brookes' paper was even read, and possibly a year before it was actually published, if we accept the statement in Oken's Isis (1830, p. 906) that the latter appeared in 1829.

Vizcacia therefore, is, probably not less than 2 years earlier than *Lagostomus*, and, as the objection to Blainville's specific name would not be considered valid by modern zoologists, the species should stand *Vizcacia maxima* (Blainville).

CURRENT NOTES ON PHYSIOGRAPHY.

BOSPHORUS, RHINE AND HUDSON.

PHILIPPSON'S 'Geologisch-Geographische Reiseskizzen aus dem Orient' (Sitzungsber. Niederrhein. Gesellsch., Bonn, 1897) include, among many other items of interest, a clear account of the Bosphorus as a partly drowned valley incised in an uplifted peneplain of deformed Devonian strata. Viewed from the summit of Bulgurlu, a low quartzite monadnock that surmounts the upland east of Skutari, the peneplain, only here and there interrupted by rounded knobs and ridges, is seen to ascend slowly northward, and then to rise in a marginal ridge of harder strata along the border of the Black Sea. The upland is generally unoccupied, being rather barren, in part from natural infertility, in part from exhaustion of the soil such as characterizes the vicinity of nearly all the great millenial cities of the Mediterranean. The Bosphorus trench has a winding course, the water surface being 200–300 met. beneath the upland. The water is generally 50 met. deep, but becomes shallower near Constantinople, as if by the washings and waste from that old city. Philippson justly compares the gorge of the Bosphorus to that of the Rhine. A still closer analogy might be found with the gorge of the Hudson, since the latter is a drowned river, deep and navigable to large vessels, while the Rhine is a running river, comparatively shallow in the gorge and interrupted by rapids and islands.

Speaking of the Rhine, mention may be made of a geological essay by Rothpletz, of Munich (Das Rheinthal unterhalb Bingen, Jahrb. k. preuss. geol. Landesanst., 1896, 10–39), in which it is shown that for about four kil. in the head of the gorge it follows close upon a narrow block between two sub-parallel faults of considerable dislocation. Although no vertical movement is proved for the block, the author concludes that there was a 'direct genetic connection' between the dislocation and the origin of the gorge, for similar disturbances seem to be wanting in the uplands (Taunus) further east. It may, however, be objected that until the date of the dislocation is shown to be recent, and until the movement of the block is shown to be downward, it is premature to make too close an association of these two phenomena. If, as is very possible, the dislocation is ancient, all sorts of happenings may have intervened before the river gained its present course; and among the factors that determined its location, the dislocation may have had a relatively subordinate rank. To place ancient structural disturbances in direct genetic connection with the location of a very modern river gorge suggests that a great many intermediate processes are overlooked.

THE GEOGRAPHY OF BRITTANY.

PROFESSOR CHARLES BARROIS, of Lille, long occupied on the intricate geology of Brittany, has recently presented a summary of its geographical divisions, with a special chapter on the influence of its physiography on its advance in civilization (Ann. de Geogr., VI., 1897, 23–64, map). The region is composed of ancient rocks, strongly folded and dislocated on east and west lines, whose trend diverges inland. To-day the surface is that of a dissected peneplain, with even skylines and a gradual descent to the north and south, the former steeper than the latter. The author believes that the ancient mountains indicated by the structure have been removed by subaërial weathering and washing, not by marine erosion. The existing longitudinal drainage lines do not occupy synclinal axes, but follow open valleys or *combes* along the strike of weak strata, after the fashion of subsequent streams. The transverse rivers, by which the inner belts of low ground are drained, cross the uplands in sharp trenches or *cluses*, across which viaducts and suspension bridges are carried above the steeples of the valley villages. These transverse streams are called *consequent*, as if determined by the lateral slopes of the original deformation (post-Carboniferous); their possible origin by superposition from a Mesozoic cover, now stripped away, is not explicitly considered. In this respect the suggested comparison of the drainage on the ancient folded structure of Brittany with the rivers of the relatively young and simple dome of the English Weald does not seem to be fully warranted.

INSEQUENT RIVERS.

INITIAL land forms, due to uplift, deformation and other non-destructive processes, are gradually carried through a systematic series of sequential changes, chiefly under the action of streams, sometimes under the action of waves, wind or ice. Omitting antecedent streams from present consideration, the first streams to be developed on an initial surface are the *consequent* streams, so named by Powell. If the valley sides of the consequent streams lay bare a disordered structure of variable resistance, gullies and ravines will grow along the guidance of the weaker structures, and thus *subsequent* streams will be developed by headward erosion; the term *subsequent* being first used in this connection by Jukes, although not in a technical sense. It sometimes happens that no guiding weak structures are revealed on the consequent

valley sides; such being the case when the rocks are either homogenous or horizontally stratified. Then the side streams, growing headwards, are accidentally located; and streams of this class have been called *autogenetic* by McGee. *Insequent* may prove to be a more satisfactory name for such streams, as it is of the same etymological family as *consequent*, *subsequent* and *obsequent;* the latter being defined in the *London Geographical Journal*, V., 1895, 134. As *insequent* has proved servicable in my lectures during the past winter, it is now submitted for trial by others.

NEW TERMS IN GEOLOGY AND GEOGRAPHY.

WITH a protest against the introduction of new terms in geology as a rallying cry, a good friend of all geologists has unfurled his banner to the breeze in a recent number of SCIENCE, as if inviting those who are of his opinion to enlist in a crusade against a threatened inundation of scientific verbiage. Those holding other opinions may prefer to enlist in friendly opposition in another camp, under the leadership of a geologist who said some years ago that he felt he had accomplished a good piece of work by introducing a new name for certain deep-seated igneous structures. For one, I dissent entirely from the dictum that new terms are 'evidently nothing more than a useless incumbrance to the science' of geology. New terms are an absolute necessity in any science that is advancing. Useless terms are of course objectionable, but who shall say which are the useless ones? New things and new ideas must have new names. There is too much good new wine to be held in old bottles. 'The common run of educated people in this country' are entirely excusable if they know nothing of such new terms as monadnock and peneplain, or of such older terms as novaculite and bauxite; for their ignorance and their opinions are irrelevant in technical matters. The investigator and the specialist must be left as free to name their conclusions as to reach them; and they, much better than any one else, can judge of the need of new names. By all means, let them be cautious and avoid unnecessary names; but unless they can number their new finds, as astronomers number new asteroids and new comets, they must name them. Having invented a new name, they may well let it take its chances in the struggle for existence. If it prove acceptable to workers in its field, it will take root and flourish; if not, it will soon wither away and be seen no more. As far as new terms in physiography are concerned, I have had a good share of amusement in watching the fate of certain words that have appeared in recent years. Some have survived and some have perished. Among several that appear to be destined to survive, although not generally used at present, let me commend 'subsequent,' 'adjusted' and 'graded' (ordinary words used in a technical sense), 'obsequent' and 'insequent' (new-made words of English form), and 'doab' and 'cuesta' (imported foreign terms), to the attention of those who maintain that new terms are evidently nothing more than a useless incumbrance to a science. It will be interesting to note the standing of these words ten or twenty years hence. The amount of attention given then or now by teachers and students to physiography—or geomorphy, as some neologists would call it—may be measured by the terseness and precision with which they express the ideas or things represented by these words and their fellows.

W. M. DAVIS.

HARVARD UNIVERSITY.

CURRENT NOTES ON ANTHROPOLOGY.

CENTRAL AMERICAN CARIBS.

THE Caribs, who spread so widely over South America, never reached any part of

North or Central America in pre-Columbian times, so far as we know. About a hundred years ago the English deported a large number of them from the island of St. Vincent to the island of Ruatan, in the bay of Hondnras. In the century which has since elapsed they have spread extensively over Central America, retaining largely their language and traits.

An interesting sketch of them is given by Dr. Carl Sapper, in the 'Internationales Archiv für Ethnographie,' Bd. X. The changes in their dialect by loss of forms and the introduction of new words from various European tongues are numerous, but its affinity to the Carib of the islands is unmistakable. Their arts also are South American.

The latter feature is further illustrated by an article from the pen of the editor of the *Archiv*, Dr. J. D. E. Schmeltz, on the utensils of the Caribs of Surinam, Dutch Guiana. It has an especial interest as tracing the development of the bird-motive in Caribbean art products. Several colored plates explain to the eye the descriptions in the text.

THE ANTHROPOZOIC FORMATION.

THE strata in geologic deposits which include the remains of man are called 'the anthropozoic formation.' To divide this accurately, with reference to sequence of time, on the one hand, and development of culture, on the other, is a leading task of the anthropologist. Professor Woldrich, of Prague, has proposed a scheme for the area of central Europe, which is published in the 'Centralblatt für Anthropologie,' 1897, Heft 2. It is useful as a general standard and it merits an epitomized reproduction here.

The Anthropozoic Formation.

I. The Diluvial Epoch.
  A. Palæolithic period.
    1. Preglacial.
    2. Glacial and Interglacial.
    3. Post-glacial.
  B. Mesolithic period.
II. The Alluvial Epoch.
  C. Neolithic period.
    1. Old or atrymolithic (no bored stones).
    2. Middle or trymolithic (bored stones begin).
    3. Late, with the stones dressed to art shapes.
  D. Metallic Period.
    1. Bronze age.
    2. Iron age.
    3. Protohistoric age.
    4. Historic age.

The author adds numerous examples of these several divisions from the layers of central Europe, and further specifications of their characteristics. He dismisses the 'hiatus' between the palæolithic and neolithic maintained by some archæologists, believing the development to have been gradual and uniform.

D. G. BRINTON.

UNIVERSITY OF PENNSYLVANIA.

NOTES ON INORGANIC CHEMISTRY.

THE statement is frequently found in the text-books that when platinum-silver alloys are treated with nitric acid a considerable quantity (5–9%) of platinum follows the silver into solution. In the Proceedings of the Chemical Society Mr. John Spiller gives the results of experiments on such alloys, containing from 0.25 to 12% platinum. In dilute nitric acid (1.2 sp. gr.) only about 0.25% of platinum was dissolved; with ordinary concentrated acid (1.42 sp. gr.) the maximum platinum dissolved was 1.25% and the average 1%. It thus appears that the ordinary statement is incorrect.

PROFESSOR RAMSAY recently read a paper before the Royal Society, detailing a series of experiments which show that helium

and argon do not pass through red-hot septa of platinum, palladium or iron. It is well known that hydrogen passes with great ease through such septa, either owing to solubility in the metal or the formation of easily decomposable compounds. Professor Ramsay's experiments imply the inability of helium or argon to form any even unstable compound with these metals or to dissolve in them at red-heat, another evidence of the inertness of these gases.

The following from the *Chemical News* deserves to be quoted in full: "Atomic Models (Patent No. 1999, 1897). A patent has recently been granted to Mr. Frederick George Edwards, of London, by which the government affords protection to his idea that all atoms can be represented by varying numbers of tetrahedrons. The germ of the idea appears to be that as there are about seventy elements known to chemists, and that the tetrahedrons can be grouped together in as many as seventy different ways, the latter can illustrate the former. This is the idea; the practice, the inventor shows, is not so simple. For instance, he says: 'Regular tetrahedrons do not fit exactly, but each tetrahedron is so nearly regular that it may be supposed that each of the elements were (*sic*) created from regular tetrahedrons in a plastic condition.' This strikes us as a beautiful example of inventing facts to fit a theory. We are glad to find that Mr. Edwards has not patented atoms *per se*, but merely the form he thinks they take, together with a few names of elements, hitherto undiscovered, but predicted by him. These are: icosagon, atomic weight, 10; *x*-odine, atomic weight, 215; and zadmium, atomic weight, 245. It will be interesting to watch the action for infringement of patent which will result if any chemist engaged in research should have the temerity or the misfortune to discover either of these predicted elements. A lithographed diagram at the end gives the *shape* of thirty-two elements, with atomic weights made to fit; we are sorry to have to record the fact that many of these atomic weights are wrong, but then so probably are the shapes."

The *Chemisches Centralblatt* gives an abstract of a lecture by L. Wenghöffer, of Berlin, on the incandescent (Welsbach) gas-light. Among many points we note the following: Auer von Welsbach is not the original discoverer of the incandescent light, but deserves the credit of having brought the light to its present perfection and made it an industrial success. The oxids for the mantles must be chosen with great care, as well as their proportions, to attain the maximum brilliancy. The best results are reached with about 99% thoria and 1% ceria. The presence of any other of the rare earths does not improve the light, and a greater or lesser proportion of ceria is detrimental. 'Russium' nitrate, the use of which has been recommended in the place of cerium, proved in one case to be a mixture of thorium nitrate with much cerium nitrate, and in another case to be a mixture of cerium and ammonium nitrates. 'Lucium' oxid is impure yttria. The best source of thoria is monazite sand, and the price of thorium nitrate has fallen from $500 per kilo at the opening of 1895 to $5 or less at present. The cause of the low price is competition, and there is no probability that the supply will diminish. The source of the cerium is the by-product of the thorium manufacture, and the price of its nitrate is steady at about $50 per kilo. The bath for saturating the mantle is a 30% aqueous solution of thorium and cerium nitrates in the proportion of 99 : 1.

From experiments on the action of ammonia on mercurous iodid, Maurice François, in the *Journal de pharmacie et chimie*, is led to the belief that the dark product formed by the action of ammonia on calomel is not a mercuro-ammonium compound, as has been

supposed, but a mixture of the colorless mercuri-ammonium compound with very finely divided metallic mercury.

N. TARUGI, who introduced the use of thioacetic acid as a substitute for hydrogen sulfid in the laboratory, has, in the *Gazzetta chimica italiana*, a study of the action of thioacetic acid on salts of bismuth. The thioacetate of bismuth is decomposed by a small amount of water with the formation of a thiobasic salt $(CH_3COS)_3$ BiS, and this on treatment with sulfuric acid gives a sulfate $(CH_3COS)_3$ Bi SO_4, and on treatment with iodin the corresponding iodid. These new compounds are of interest as being the first compounds of quintivalent bismuth in the marsh-gas series.

J. L. H.

SCIENTIFIC NOTES AND NEWS.

THE Senate has agreed to the provisions in the tariff bill admitting free of duty books in print more than twenty years, books in foreign languages and such as are devoted to scientific research, and books and scientific instruments imported for public and educational institutions.

PERHAPS the most noteworthy additions to the United States National Museum during recent years have been the rich collections of pre-historic pottery, made in the pueblo region, during the last two seasons, by Dr. J. Walter Fewkes, of the Bureau of American Ethnology. The success attending his operations in the past has led to a provision for continuing the work, and he has recently set out to the field for the third time. His design is to survey and excavate the ruins known among the Indians as Kintiel, near Navajo Springs, Arizona. He is accompanied by Dr. Walter Hough, of the United States National Museum.

THE keen appreciation of the importance of research on the part of Secretary Wilson has already given fresh impetus to various lines of scientific work in the Department of Agriculture. The more important operations are carried forward without change of personnel; it seems to be the policy to maintain and strengthen the bureaus built up through the zeal and ability of well-known scientific men; and, at the same time, scientific character is given to certain of the lines of work hitherto regarded as administrative. One of the recent changes is the appointment of Mr. John Hyde as Statistician of the Department. Mr. Hyde became widely known through his connection with the Eleventh Census, and he has more recently been known in scientific circles as editor of the *National Geographic Magazine* and as a writer on political economy.

MAJOR J. W. POWELL is on the coast of Maine, engaged in researches concerning shell mounds, in the interest of the Bureau of American Ethnology.

PROFESSOR SOUILLARD, astronomer at Lille, has been elected a corresponding member of the Paris Academy of Sciences.

DUBLIN University has conferred the degree of D. Sc., on Professor William Ramsay, Major P. A. M'Mahon, D.D., and Professor Wilhelm His, of Leipzig.

DR. RUDOLPH LEUCKART and Dr. Karl Neumann have been made Knights of the Prussian Order of Merit in Science and Art.

THE Royal College of Surgeons of England has conferred the John Tomes prize on Mr. C. F. Tomes, F. R. S.

THE *Naturwissenschaftliche Rundschau* states that, at a recent meeting of the Academy of Sciences of Vienna, Ritter v. Arneth was reëlected President; Dr. Suess, Vice-President; Professor Huber, General Secretary, and Dr. Hann, Secretary of the Mathematico-Physical Section. Dr. Gautsch v. Frankenthurm and Dr. Exner, of Innsbruck, were elected corresponding members; Lord Lister, honorary foreign member; and Dr. Vogel, of Pottsdam; Herr Karpinsky, Director of the Geological Institute of St. Petersburg; Dr. Gegenbauer, of Heidelberg, and Herr Brioschi, of Milan, corresponding members.

M. LE GÉNÉRAL DE TILLO announced at a recent meeting of the Paris Academy of Sciences that the sum of 25,000 francs had been subscribed in Russia to the Lavoisier monument fund.

M. Falguières has been commissioned to design the Pasteur statue to be erected in Paris, for which 297,000 francs has been subscribed.

The United States Civil Service Commission will hold an examination on July 20th to establish a register of eligibles for the position of industries in the Indian school service. The subjects of the examination will be penmanship, spelling, methods of manual training, arithmetic, geometry, geography, industrial economy, mechanical or industrial drawing (one optional), free-hand drawing and physics. There is a vacancy at the Indian school at Perris, Cal., the salary of which is $840 per annum.

We regret to record the deaths of DeVolson Wood, professor of mechanical engineering at the Stevens Institute of Technology, Hoboken, New Jersey, on June 27th, at the age of sixty-five years; of Professor Julius von Sachs, on May 29th, at the age of sixty-five years; of the Rev. Alexander Freeman, on June 12th, at the age of fifty-eight years. Mr. Freeman was at one time deputy for the Plumian professorship of astronomy at Cambridge, and was a fellow of the Royal Astronomical, Mathematical and Physical Society; of Dr. Peter Von Tunner, at the age of eighty-nine. Dr. Von Tunner founded, in 1840, the school of mines at Leoben, in Styria, and was the author of many contributions on the metallurgy of iron and steel.

The London *Times* reports that Dr. Wölfert and an assistant named Knabe were killed on June 12th while making trial of a navigable balloon invented by Dr. Wölfert. The balloon was being exhibited at Berlin before the officers of the ballooning section of the army, when the gas was ignited by the benzine used in the motor.

Commissioner Herrmann, of the General Land Office, has, it is said, submitted to the Secretary of the Interior a report regarding the rules and regulations for the government of the forest reserves, with special reference to the parts available for mining, grazing and agriculture.

It is said that the Legislatures of the States of New York and New Jersey will be asked at their next sessions to provide for the building of a broad roadway 15 miles long at the base of the Palisades and to protect them from injury by quarrying.

We are glad to learn that on June 19th a Zoological Club was organized at Springfield with nineteen members. The first officers are: President, W. W. Colburn; Secretary, Miss M. A. Young; Treasurer, Miss L. I. Mattoon; and Dr. George Dimmock and Miss M. A. Booth, additional members of the Executive Committee.

The Park Board of New York City has adopted the plans for the buildings of the new Botanical Gardens in Bronx Park, as modified by the directors in accordance with the advice of a committee consisting of Professor Sargent and Messrs. Olmsted, Hastings and Parsons.

The library of Columbia University has received from an anonymous donor 387 books, valued at $6,000. These include a number of valuable works in natural history, such as Audubon's Quadrupeds, Sepp's Nederland'sche Insekten, Gould's Humming Birds and Levaillant's Oiseaux d'Afrique.

It is stated in *Die Natur* that Dr. O. Zacharias reported at a recent meeting of the Saxon Fisheries Association that the Prussian government would, after October of next year, give assistance to the biological station at Plön.

The Boston *Transcript* states that an expedition under the charge of Mr. C. M. Harris, of Angusta, Me., has sailed from San Francisco for the Galapagos Islands, with a view to studying their fauna and flora. It is said that Messrs. E. D. Hall, of Dartmouth; F. P. Duowle, of Providence, and R. I. Beck and R. H. Beck, of California, are members of the expedition, and that the expenses are defrayed by Mr. Walter Rothschild.

The Australasian Association for the Advancement of Science will, as we have already announced, hold its seventh session at Sydney, commencing January 6, 1898. Professor A. Liversidge is the President-elect. The President and officers of the several sections are as follows:

Section A—Astronomy, Mathematics and Physics. President, R. L. J. Ellery, C.M.G., F.R.S.; Secre-

taries, Professor A. Threlfall, M.A., J. Arthur Pollock, B.Sc.

Section B—Chemistry. President, T. C. Cloud, A. R.S.M., F.I.C., F.C.S.; Secretary, W. M. Hamlet, F. I.C., F.C.

Section C—Geology and Mineralogy. President, Captain F. W. Hutton, F.R.S., F.G.S.; Secretaries, Professor T. W. E. David, B.A., F.G.S., E. F. Pittman, A.R.S.M., F.G.S.

Section D—Biology. President, Professor T. J. Parker, D.Sc., F.R.S.; Secretaries, Professor W. A. Haswell, M.A., D.Sc., F.L.S., J. H. Maiden, F.C. S., F.L.S.

Section E—Geography. President, to be appointed. Secretary, H. S. W. Crummer, Secretary Royal Geographical Society of Australasia.

Section F—Ethnology and Anthropology. President, A. W. Howitt, F.G.S.; Secretary, John Fraser, B.A., LL.D.

Section G—Economic Science and Agriculture. President, R. M. Johnson, F.L.S.; Secretaries, R. R. Garran, B.A., F. B. Guthrie, F.C.S.

Section H—Engineering and Architecture. President, H. C. Stanley, M.I.C.E.; Secretaries, J. W. Grimshaw, M.I.C.E., M.I.M.E., H. C. Kent, M. A.

Section I—Sanitary Science and Hygiene. President, Hon. Allan Campbell, M.L.C., L.R.C.P.; Secretary, Dr. F. Tidswell, M.B.

Section J—Mental Science and Education. President, John Shirley, B.Sc.; Secretary, Professor Francis Anderson, M.A.

THE business meeting of the British Medical Association will be held in London on July 27th, to discuss the reports of the Council and of the various committees, and will then adjourn for the meeting at Montreal, beginning on August 31st. The meeting at Montreal, the first to be held outside the United Kingdom, promises to be very successful. The Dominion government has voted a sum of £1,000 to the reception fund, the government of the Province of Quebec £500, and other public bodies have been equally generous. The *British Medical Journal* has published an extended list of those who have signified their intention to be present, including the names of many eminent British physicians and men of science.

THE current number of *Nature* contains the first of a series of articles by the editor, Professor Norman J. Lockyer, on the approaching total eclipse of the sun. It appears that the weather prospects of the eclipse to be observed in India, on January 22d of next year, are extremely favorable. The meteorological reporter to the government of India states that the chances of any given day in January being rainy in Konkan is less than one in one hundred and fifty. The Joint Committee of the Royal and Royal Astronomical Societies have determined to send out three parties to observe, one on the coast and two inland, at stations to be subsequently decided upon. It has been arranged that the party from the Solar Physics Observatory will occupy the coast station if the Admiralty can grant the use of a man-of-war to allow an attempt to be made to repeat the *Volage* programme of 1896. In this case the station will possibly be the old fort at Viziadurg. The land parties, which will include the Astronomer Royal, Professor Turner and Mr. Newall, representing the Observatories of Greenwich, Oxford and Cambridge, together with Dr. Common and Captain Hills, occupy stations near the central line on the railways shown on the map (Fig. 1).

IT is reported in the daily papers that Dr. David Starr Jordan stated before leaving for Alaska that, as the British government has not come to satisfactory terms with the United States for the protection of fur seals in Bering Sea, the United States will begin this summer, through the Fur Seal Commission, the work of branding the female seals in the Pribilof Islands. This will spoil the skins of branded seals and stop pelagic sealing by making it unprofitable. One of Dr. Jordan's assistants, Elmer Farmer, expert electrician, has invented an electrical machine for branding seals, and if it prove satisfactory it will do a great deal toward settling the seal question. There is a possibility that the female seals may be coralled on one of the islands during the sealing season.

AN International Congress of Technical Education took place in London on June 15th, 16th, 17th and 18th. M. Saignat, the retiring President, made some remarks in introducing the President, the Duke of Devonshire, who addressed the Congress at length. Papers were presented by Professor Otto N. Witt, of the Berlin Polytechnic Institute; Dr. H. E. Arm-

strong, Sir Henry Roscoe, Professor G. Lunge of Zurich, Mr. G. R. Redgrave and others. The United States appears not to have been represented by delegates.

A DECREE has been signed by the President of the French Republic regarding medical experts before the Courts of Algeria. It appears that such experts must be appointed at the beginning of each year, and receive a fixed compensation for such services as are rendered.

UNIVERSITY AND EDUCATIONAL NEWS.

THE will of the late Dr. George Edwards leaves $50,000 to Princeton University for the endowment of a chair in American History and $2,500 for other purposes.

AT the commencement exercises at Beloit College, Dr. G. K. Pearsons presented the College with $30,000 to build a woman's hall. Dr. Pearson's previous gifts to the College amount to $250,000.

PRESIDENT SEELEY announced at the commencement exercises of Smith College that $10,000 had been offered to the College for the erection of a building for the scientific laboratories on condition that $9,000 should be subscribed by the alumnæ.

UPON the recommendation of the Faculty of the College of Physicians and Surgeons, Columbia University, the title of the chair of chemistry and medical jurisprudence was changed to that of physiological chemistry. The chair has not yet been filled.

DR. THOMAS S. FISKE, adjunct professor in mathematics in Columbia University, has been promoted to a full professorship.

PROFESSOR M. V. O'SHEA, of the Buffalo School of Pedagogy, has been appointed to the chair of pedagogy in the University of Wisconsin.

THE trustees of Oberlin College have elected as President, Dr. William Slocum, now President of Colorado College.

DR. FUCHS has been promoted to an associate professorship of paleontology in the University at Munich. Dr. G. Boccardi has been appointed associate professor of microscopical anatomy at the University of Naples, and Dr. J. Szadowski associate professor of geology at the University at Klausenburg. Dr. E. Wiechert has qualified as docent in physics at the University at Göttingen, Dr. Adolf Marcuse as docent in astronomy in the University of Berlin, and Dr. Max Dettrich as docent in chemistry in the University at Heidelberg.

DISCUSSION AND CORRESPONDENCE.

PALEONTOLOGICAL AND EMBRYOLOGICAL METHODS.—A REJOINDER.

ALTHOUGH I would have preferred to postpone the discussions on the systematic position of Tarsius which was commenced a few months ago (SCIENCE, February 12th, April 2d, April 23d) till the publication of a more extensive memoir which is at present in preparation, I may yet be allowed to say a few words in reply to Mr. Earle's "claim that the paleontological method in determining phylogeny is more nearly accurate than the embryological, as in the latter many characters are lost and innumerable cænogenetic variations are introduced which the embryologists often cannot distinguish from real homogenetic structures."

Leaving aside the somewhat loose constructions as to a 'method' in which 'characters are lost and 'variations introduced,' and considering it to be the writer's intention to point out to us that the facts which are brought to light by embryological research are for many reasons less reliable than those which we owe to paleontological science, I would wish the readers of SCIENCE to follow up that line of reasoning a little more closely. For it would seem to me that if we run a great risk of going astray in comparing the characters of the early embryos with each other because these characters are influenced by 'cænogenetic variations,' it is *a fortiori* none the less dangerous to compare the adult structures which develop out of these embryonic rudiments and upon which the same caution should necessarily be brought to bear. In that respect a paleontologist can hardly be said to be in a safer corner than an embryologist.

When, however, the embryologist wishes to construct phylogenetic trees out of his ontogenetical data I quite agree with Mr. Earle

that he is on less stable ground than the paleontologist who, for example, in the case of the horse has dug up the actual tree out of the successive Tertiary strata. Ontogenetic development undoubtedly makes us acquainted with cænogenetic variations which have been the cause of many a premature conclusion. In Tarsius, however, it was not to any changes, hypothetical or otherwise, that attention was directed by me, but on the contrary to a *persistence* of a most unexpected *agreement* which reveals itself in the numerous details of a complicated arrangement, such as is only found in man, the monkeys (as far as investigated) and Tarsius. And whoever calls attention, as Mr. Earle does, to the liability of embryological structures to vary must necessarily recognize the high value of those cases in which there is evidence not of variation, but of stability. It is because of this stability that Tarsius should be placed somewhere between (though not, of course, in the direct line) the Anthropoids and their unknown Mesozoic ancestors with a non-diffuse placentation.

Mr. Earle's assumption that the diffuse stage of placentation of some of the Anthropoids is apparently directly comparable to that of the Lemurs is invalidated by recent researches on early human plastocysts, researches which all tend to confirm the objections against such comparison which were raised by me in 1889 (*Quar. Journ. of Micr. Science*, Vol. 30, p. 364 and p. 382).

Finally, Mr. Earle's contention "that it has not been shown as yet that the placenta in the lemurs is not a derivative of the chorion, as in the apes," although perfectly justified when it was written, is nevertheless unsupported by the actual facts.

Since Milne-Edwards has emitted the opinion which Mr. Earle cites in a footnote, the Lemurine placentation has been again described in the *Quart. Journ. of Micr. Science*, Vol. 36, p. 90, pl. 9–12. In addition to that I may now state, on the strength of observations as yet unpublished, that in a true Lemur, such as Nycticebus, the fusion of the vascular walls of the allantois with the non-vascular diplotrophoblast can be followed step by step. It is a totally different process from that by which the vascular chorion of man, monkey and Tarsius comes into existence.

Another important point of difference between Lemurs and Tarsius which I have only lately been able to establish, thanks to the preparations just alluded to, is the presence in Nycticebus of a typical proamnion, so common among the lower Placental Mammalia and wholly absent in Tarsius and in man.

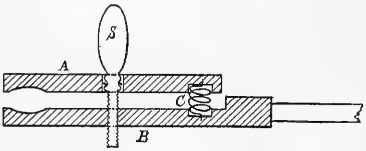
UTRECHT, May 18, 1897.

A CLAMP FOR FRAGILE GLASSWARE.

WE have for some time been using a simple modification of the well-known wood clamp, which has given sufficient satisfaction to warrant a brief description. The clamp is constructed for holding light tubular glassware like Crookes' tubes, and it acts at once as a screw clamp and a spring clamp. The jaws, *A*, *B*, are set at any desirable distance apart by the screw, *S*. Loose pins allow *A* to rock slightly in the plane of the screw. The spring, *C*, in the rear presses strongly outward. When set, the jaws may thus be further opened (like a spring clip) by compressing the spring, *C*, with the hand. The jaws may be either flat or notched and need no packing.



This clamp has the following advantages: By aid of the screw the clamp may be adjusted to fit any tube up to over 2 inches for the ordinary size of clamp. The tube is removed or again inserted by mere pressure of the hand in the rear end of the jaws, *A*, *B*; the gradual counter-pressure of the spring prevents crushing of fragile apparatus, even when no cork or rubber cushion is used, while it can be intensified to hold very heavy objects.*

CARL BARUS.

BROWN UNIVERSITY, PROVIDENCE.

* The clamp can be obtained from Eimer & Amend, in New York.

MERRILL'S 'TREATISE ON ROCKS.'

TO THE EDITOR OF SCIENCE: In animadverting on the defective English of Professor Merrill's 'Treatise on Rocks,' etc., in your current number, Mr. Woodworth says: "In the case of other quotations it is sometimes doubtful as to which author the work in a certain district is to be referred" (page 996). Will the author of this sentence kindly express his idea in German or French or Chinook, and thereby oblige half a dozen readers who find themselves unable to grasp his exact meaning?

W J MCGEE.

WASHINGTON, D. C., June 26, 1897.

THE TRIAL OF THE CROSSLEY REFLECTOR OF THE LICK OBSERVATORY.

A MATTER relating to work at the Lick Observatory (with reference to the trial of the three-foot reflecting telescope presented to us by Mr. Crossley, of England, in 1895) has lately been discussed in newspaper press-dispatches in rather a one-sided fashion. I desire to say that the questions involved have been passed upon by the Regents of the University of California, who have, unanimously, approved my action. The decisions of the Regents have not been spoken of in press-dispatches, which is my reason for writing this note.

EDWARD S. HOLDEN.

THE LICK OBSERVATORY, June 21, 1897.

SCIENTIFIC LITERATURE.

Our Native Birds of Song and Beauty. By HENRY NEHRLING. Published by George Brumder, Milwaukee. Vol. II., 4°. Pp. 453; 18 colored plates. Complete work in 16 parts, $16; bound in 2 vols., library binding, $18; handsome dark leather binding, $22.

The second complete volume of this admirable work, some of the separate parts of which have been already noticed in these pages, has now been issued to subscribers. The two volumes make a handsome addition to any library and should be in the possession of all lovers of birds. The work contains no technical matter, and little effort has been made to incorporate the latest facts bearing on the geographic distribution of the various species, the aim being to supply trustworthy accounts of the life histories of the birds in relation to their environment and in their relations to man. Mr. Nehrling has the instincts and sympathies of a naturalist. He is evidently a botanist and musician as well as an ornithologist, and his descriptions of bird life are generally woven in with pictures of shady ravines and forest glades or flowery dells where the birds and plants and landscape are seen together as they are in nature. His residence in widely separated localities—Wisconsin, Missouri, Texas and Florida—has enabled him to become familiar with a large proportion of the birds he treats, and his personal knowlege is supplemented by copious extracts from the writings of others. Special emphasis is given to economic relations and breeding habits.

As stated in notices of the earlier parts, the illustrations, all of which are colored, show the birds in natural surroundings and are of two kinds: plates of single species, mostly by Robert Ridgway; and mixed plates, by Mützel and Göring. Some of Mr. Ridgway's plates of single species are among the most charming bird pictures I have ever seen. Those of special excellence in the present volume are the Black Rosy Finch (*Leucosticte atrata*) and Dickcissel (*Spiza americana*)—the former on a mountain top, the latter in a clover field. Three of the mixed plates by Mützel are worthy of special mention; Plate XXI, a group of showy winter birds—the Pine Bullfinch, White-winged Crossbill, Redpoll, Evening Grosbeak, Nuthatch and Chickadee—in the top of a snow-covered spruce; Plate XXVIII, the Blue Grosbeak and three species of *Passerina*—the Indigo Bird, Painted Bunting and Lazuli Finch; Plate XXXVI, six species of brilliantly colored Woodpeckers.

Even in the mixed plates the attempt has been made to group the species in appropriate surroundings, and much pains has been taken with the landscape and vegetation. Thus, Göring's picture of the Scissor-tailed Flycatcher, Green Jay and Verdin shows these birds (and one or two others) among cactuses, flowering agaves, and aborescent yuccas with a barren range of desert mountains in the background.

Although the plates are of uneven merit, even the poorest are sufficiently good to serve the purpose of identification and will be most

helpful to the student. We take pleasure in commending the work to nature lovers, and particularly to the large and healthful class of of out-door students of birds.

C. H. M.

The Present Evolution of Man. By. G. ARCHDALL REID. London, Chapman and Hall. 1896. pp. 370.

The work which has appeared with the above title consists in fact of two parts; up to p. 196 it has reference to organic evolution in general, and only the remaining portion, pp. 197–370, treats especially of the evolution of man. In the earlier part of the work there is given a very excellent discussion of the broad principles of evolution, and particularly of the reasons which lead to the conclusion that acquired characters are not inherited by other than the lowest organisms. The argument against the transmission of acquired characters, as ordinarily understood, appears to the writer conclusive, and he would commend it to the neo-Lamarckians for dissection. It is also well shown that under ordinary circumstances natural selection works upon normal variations, and not upon those which occur only at infrequent intervals. Much stress is also laid, very justly, upon the importance of characters which are normally acquired, and of the power of acquiring them.

An interesting argument runs as follows: Inasmuch as progressive or new variations may be in all directions, but atavistic variations are in one direction—towards the ancestry—there will be a tendency, in the long run, *in the absence of selection*, to revert to a more primitive condition, owing to the dominance of the atavistic variations. When the evolution has been very slow, as with certain Brachiopoda, the reversion will be scarcely noticeable, but when it has been very rapid, as with many domesticated animals, the reversion will be rapid and striking. All this appears to accord with the known facts, but to the present writer it seems an inadequate statement of the actual course of events. Mr. Reid says: "In every species natural selection as a cause of evolution, and atavism as a cause of retrogression, are constantly at war." It does not seem to me that this is necessarily the case, but that, on the other hand, atavistic variations may be themselves selected. The germ, it must be supposed, contains units representing many phases of existence, some of which have been held over, undeveloped, through many generations, while others are new. When one of the latter develops we say the variation is a progressive one; when the former develop we call the result atavism. It is reasonable to suppose that environmental and germinal selection are the factors which determine which of its possible developments the germ shall undergo. That is to say, there are two factors involved, one the relative vitality or growth-force of the several germinal elements, the other the environment favoring one or the other in their struggle This same struggle, in various phases, goes on through life; for example, many people have two or more talents, which cannot be fully exercised simultaneously; other things being equal, the strongest will prevail, but how often the environment steps in and dictates which of the possible paths of life shall be followed.

This being made clear, it is evident that atavism increases the range of possibilities of any given germ, and thus may be highly advantageous. Especially is this the case when the environment is changeable, as with seasonally dimorphic butterflies, one phase of which is probably in most cases older than the other. My own studies of bees have led me to believe that many of the specific characters had their origin in atavistic variations, because it often happens that a character will appear in two different groups independently, and yet be so striking and definite as to suggest that it must have existed in a common ancestor, though not in the immediate ones.

How, then, as to atavism in the absence of selection? It is perfectly obvious that any given adult individual does not, under existing circumstances, represent the average potential, if one may so express it, of its race. In the first place, the individual is probably a survivor out of many—has been the subject of natural selection. In the second, it represents only one (selected) phase of the many that were possible to the germ. In the total absence of selection (an impossible thing) we should obviously

get the actual mean, or a series of individuals symmetrically arranged around that mean. This would involve more or less atavism, because the potentialties of the germs are derived from past generations, and include many repetitions, more or less complete, of phases which have lately, owing to the incidence of selection, been permitted no development. But I cannot see, with Mr. Reid, that there would be unlimited atavism, because when the atavistic changes had proceeded from B to A, the B-features would become ancestral, and a new atavism, from A to B, would appear. Thus at some point there would be reached a condition of equilibrium, and the tendency to vary in any particular direction would be lost. Existing species may be compared to elastic bodies under stress, the stress being natural selection. When the stress ceases, there is contraction until the condition of equilibrium is reached, but certainly not indefinite contraction.

The second portion of the book consists of a discussion of human evolution against zymotic diseases and narcotics. Mr. Reid argues that the way to tell in what direction the evolution of a species is tending is to observe the causes of mortality. Applying this test to man, he concludes that as disease is the principal cause of death it must be against disease that we are evolving. He then proceeds to show that those races which have long been subjected to a particular disease, *e. g.*, malaria or consumption, have acquired a relative immunity from it, or at least a power of enduring its attacks. The whole matter is set forth very clearly and is well worth reading. While it cannot be denied that the factor of zymotic disease is an extremely important one, hitherto generally overlooked in discussions on human evolution, I must say that I think Mr. Reid himself has overlooked some not less important factors. The 'social efficiency' of a people, as Mr. B. Kidd rightly insisted, is a factor of immense importance. Thus, in this very matter of zymotic diseases, how greatly is the death rate in an epidemic (and the existence of the epidemic itself) influenced by the social condition of the people, and even by their intellectual and moral condition, as reflected in the municipal government and sanitary arrangements! Thus, while, as Mr. Reid shows, the negro is under identical conditions far less affected by malaria than white people, Dr. J. S. Billings has to report, in summing up the statistics for 28 cities of the United States, that the deaths from malarial fever were more than three times as numerons, in proportion to the population, among the colored people as among the whites. It is fair to state that under the term 'colored' he includes the Chinese, etc., but the difference is conspicuous in those cities which are known to contain a large negro population. Mr. Reid may reply that sanitary arrangements and forms of government, affecting all, select nobody; but certainly they do select the citizens of one town, State or country as against others, or those of the rural districts as against the towns. Thus the population of large cities, like London, is perpetually replenished from the rural districts. A pure-bred cockney of the fourth generation is said by J. M. Fothergill to be very rare. Further, as Dr. Billings has shown (11th Census of the United States) the death-rate in every large city varies enormously in the different wards, and this must be due mainly to the mode of life of the people, their food, sanitation, and other matters directly connected with social efficiency. Still again, there is a tremendous proportion of infant mortality, a large part of which must be due to unfavorable conditions of the mother or child. Thus it must necessarily be that, while there are inequalities in morality and intelligence, the most moral and the most intelligent races or groups of people will be favorably selected in the struggle for existence.

The whole subject is one of immense complexity, and in studying the statistics one has to be constantly on the lookout for sources of error, which are numerous and confusing. But there is no doubt that Mr. Reid's discussion is a valuable one, if only it draws attention to matters which have been too much overlooked.

The final portion of the book, treating of evolution, against alcohol and other narcotics, seems to me to contain a fundamental error. It is assumed that a desire for alcohol is inherent in the human race, and that, since the substance cannot be banished, our only salvation is to gradually acquire a toleration of it, as of a

zymotic disease. It is shown that certain races are on the way to acquire such toleration, and in the presence of alcohol suffer much less than others. An obvious difficulty here is to explain how, under the influence of natural selection, this highly pernicious craving for alcohol arose. Mr. Reid says: "It can have arisen only as a bye-product of mental evolution, a bye-product which, in the absence of narcotics, was harmless, but which in the presence of them is harmful." This surely is a very far-fetched supposition, since it is implied that the craving for alcohol developed in the absence of that substance! To the present writer it appears evident that the human race has no natural craving for alcohol at all, but it has a craving for excitement and other states of mind which may be induced artificially, and that when the natural exercise of highly valuable faculties is denied, as is so often the case in our present civilization, artificial means, often highly injurious, will be resorted to. It will apparently sometimes happen that when an artificial stimulus is persisted in for a long while, and is not in itself injurious, it will become a necessity, just as clothes have become necessary to a large portion of mankind. As an instance of this, we may cite the use of hot flavoring substances (as pepper) by inhabitants of warm countries to promote digestion. It is conceivable also that a race might acquire considerable toleration of alcohol, and at the same time lose the power of acting efficiently except under its influence, so that a member of the race, separated from his bottle, would be powerless! But it is perhaps more likely that the process would be just that which Mr. Reid describes as inevitable, namely, that the desire for alcoholic stimulation would be lost, while at the same time the effects of drinking a given quantity of alcohol would become less. This is regarded by Mr. Reid as very desirable, but what if it means the destruction of a valuable faculty, which, rightly exercised, might have been once more, as originally, of great importance to the race? Put it in this way: The wretched laborer of a crowded city, overworked and underfed, desires to escape from his environment—desires, if only for a brief period, to be free. Alcohol gives him a temporary means of escape, but at a frightful cost. It is deplorable that he should seek it, but how much more deplorable it would be if he should cease to care—if he should become degraded to a mere machine, accepting without thought the suppression of three-fourths of his natural activities? Surely the remedy is not, as Mr. Reid supposes, to eliminate those who wish to drink, but to find the means of living full and active lives, in the natural exercise of all our functions.

MESILLA, N. M., June 8, 1897.

SOCIETIES AND ACADEMIES.

MEETING OF THE NEW YORK SECTION OF THE AMERICAN CHEMICAL SOCIETY.

THE New York Section of the American Chemical Society held its June meeting on the 11th inst., preceded by a dinner, at which thirty members participated, including the President of the General Society, Dr. C. B. Dudley. The meeting was called to order in the chemical lecture room of the College of the City of New York, at 8:30, by the chairman, Dr. William McMurtrie, who then invited Dr. Dudley to preside.

The death of Professor C. R. Fresenius at Wiesbaden was announced, and the Secretary was authorized to cable the regrets and condolence of the Society to his sons. An obituary notice of Dr. Carl H. Schultz was read by Dr. A. P. Hallock, after which the papers of the evening were read as follows:

F. S. Hyde, 'Comparative Tests for Identification of Some Medicinal Carbon Compounds.' E. G. Love, 'Note on Analysis of Cheese.' Benj. C. Greenbergh, 'Determination of Dextrine in Presence of Sugars.' Gustav Volckening, 'Novel Mechanical Arrangement of Fat Extraction Apparatus.' L. Reuter, 'Demonstration of Some Chloroform Compounds and of Some of Baumann's Thioaldehydes.' W. E. Chamberlin, 'Calibration of Volumetric Apparatus.' C. A. Doremus, 'Method of Collecting and Analyzing Gases contained in Canned Goods.'

It was stated by the chair that forty papers had been presented before the Section during the winter, a number considerably in excess of

any previous session, and the attendance at the meetings had averaged about fifty, also an increase over previous records. The Section was then adjourned until October.

Durand Woodman,
Secretary.

TORREY BOTANICAL CLUB, MAY 11.

Dr. N. L. Britton presided in absence of the President. Three new members were elected. Three successful field-meetings were reported. Resolutions were adopted commemorative of Dr. Emily L. Gregory, the late honored professor of botany at Barnard College, an active worker in the Club. Announcement was made of the recent gift, by President Low to the botanical department of Columbia, of a valuable set of water-color plates prepared by the late lamented Wm. Hamilton Gibson, in illustration of his projected work on mushrooms.

The paper of the evening followed, by Mr. Marshall A. Howe, entitled 'A Preliminary Comparison of the Hepatic Flora of California with that of Europe and of the eastern United States.''

The total number of Californian species now known is 77, of which 45 occur in the Mediterranean region, but only 37 in the Gray-Manual region of the United States.

It was shown that the hepatic flora of California has more in common with that of northern and central Europe than with that of the eastern United States, and is still more allied to that of the Mediterranean region. In particular, species of *Asterella* and *Riccia* are better developed in California and southern Europe than in the eastern United States.

The apparent absence in California of *Bazzania* and *Mylïa*, which are especially characteristic of medial and boreal regions, serves to heighten the similarity to southern Europe.

The paper was followed by exhibit of photomicrographs of sections of Cryptomitrium, illustrating the development of the archegonia. In the discussion following, Professor Underwood said that the Hepatic species are most numerous in the Amazon region, the eastern slope of the Andes, and in Java. Insular tropical regions have furnished many where examined, as Cuba and Jamaica. Quite a number are peculiar to Australia. New Zealand is well supplied with species. Many have been recently collected in Africa, and have been described by Herr Stephani, of Leipsic, whose industry has doubled the number of described Hepaticæ. As a whole, the maximum development of the Hepaticæ is tropical, though some genera and certain groups within genera are wholly high-temperate or subarctic.

Professor Britton, remarking the indications of circumboreal and circumtropical distribution of certain species, referred to the argument for an equatorial distribution of flowering plants and of ferns, and queried if there were anything corresponding among Hepaticæ. He expressed the belief that it is the immediate environment which at present exerts the principal influence on distribution, whatever the original cause or mode of distribution may have been.

Professor Underwood referred to the influence of the Gulf Stream in permitting the existence of the subtropical genus *Lejeunia* on the coast of Ireland, a genus not elsewhere found in Europe. Comparing the Hepaticæ of Florida, they are only in part known; a few species are in common with the Appalachian flora; most of the Florida Hepaticæ are close-creeping forms found on bark, as *Frullania* and *Lejeunia*, having water-sacs on their leaves as aids in resisting drought. Some tropical *Marchantiaceæ* occur in Florida, and also, especially, species of *Riccia* and *Anthoceros*. *Thallocarpus* is known only from Florida and South Carolina.

*THE PHYSIOLOGY OF INTERNAL SECRETIONS.**

WE owe the term 'internal secretions' to Brown-Séquard,† by whom it was first used in published communications dating from 1891. The essential idea conveyed by the expression, however, is not new, as it has been stated more or less clearly by many previous writers in their speculations upon the probable functions of the so-called ductless or vascular glands. It had long been recognized that these glands possess no excretory ducts, and that, therefore, whatever secretion they may produce probably enters the blood either directly or by way of the lymph. Haller* is credited with stating this view with regard to the thyroid as early as 1776, and according to Pettit† a similar view was advanced by Schmidt in 1785 with regard to the suprarenals. Toward the middle of the present century this belief was generally accepted for such glands as the thyroid, suprarenals, thymus, hypophysis cerebri and spleen, but as early as 1869 Brown-Séquard seems to have suggested the view that all glands, whether possessed of excretory ducts or not, give off something to the blood that is of importance in the general nutrition of the organism. From 1889 his ideas took definite shape in numerous publications‡ upon the physiological effects of injections of extracts of the testis. At first he did not use the term internal secre-

*Paper read at the 4th Triennial Session of the Congress of American Physicians and Surgeons.

† Brown-Séquard and d'Arsonval: Comptes rendus de la Société de Biologie, 1891.

* Jones in Todd's Cyclopædia of Anatomy and Physiology: Article on Thyroid Gland.

† Pettit: Recherches sur les capsules surrénales, 1896—Paris. Thèse de la Faculté des Sciences.

‡ Brown-Séquard: Archives de Physiologie normale et pathologique 1889–92.

tion, and seems to have held the view, so far as the testis is concerned, that the material furnished to the blood is absorbed from the external secretion and is normally carried off in part in this secretion.

During this same period the brilliant results of the experiments made upon the thyroid glands and the pancreas were forcing themselves upon the attention of physiologists, and these results, together with his own experiments upon the extracts of testis and ovary, and his previously expressed belief as to the possible effect exercised by all glands upon the composition of the blood, seem to have led Brown-Séquard to the generalization expressed in the happy term 'internal secretion.' The term as used by him was not restricted to the glandular tissues alone, but was meant to signify that all the tissues in the body furnish something of special importance to the blood—that, in fact, every act of nutrition is accompanied by an internal secretion This broadening of the term to apply to all the tissues is logical, perhaps, but it must be admitted, I think, that so far as our actual knowledge goes it is not justifiable. The evidence derived from experimental investigations and clinical observations indicate that many, although not all, of the glandular tissues of the body as a result of their normal metabolism add something to the blood or affect its composition in some way, and that this activity is either essential or helpful to the maintenance of the normal functions of the organism. In this list we can place such glands as the liver, pancreas, thyroid and parathyroid bodies, suprarenal bodies, hypophysis cerebri, and probably the ovary, testis, thymus and spleen. But I know of no observations that force us to entertain a similar belief with regard to the non-glandular tissues, such as muscle, nerve and connective tissue.

So far as I am aware, there is no authorized definition of the term internal secretion, but, if we adhere closely to the facts in the case, the expression may be interpreted to mean certain products that are elaborated by gland cells from material furnished by the blood, which are afterwards passed back to the blood or lymph stream to subserve some function in general or special nutrition. From the standpoint of mechanism of secretion a useful distinction has been drawn between these internal secretions and secretions of the usual kind, or external secretions. The latter are in all typical cases poured out upon a free epithelial surface that communicates with the exterior, while the internal secretions are discharged upon the close endothelial surfaces of the blood and lymph vessels.

The definition given by Brown-Séquard, as we have seen, attributed internal secretions to all tissues. As a part of this general conception he was led also to restate what appears to have been a dream of the older physicians, namely, the view that all animal tissues might and ought to be employed in special cases as means of medical treatment, extracts of each organ or tissue being recommended for the particular disease supposed to be due to disturbance of function in the corresponding tissue. This general conclusion seems to have been a wide induction upon the basis of the incomplete facts known at that time with regard to the therapeutical use of extracts of thyroid and testis. It was not entirely justified by actual experience then or now, but the attractive possibilities it presents have doubtless been the cause of much of the general interest manifested in the subject of internal secretions. A new field, hitherto almost unexplored and full of promise for the discovery of medical specifics, seemed to be opened to the medical profession, and much activity has been exhibited in exploiting the possibilities of this kind of therapeutical treatment for

which the names *opotherapeutics*, *organotherapeutics* and *histotherapeutics* have already been suggested.

It must be borne in mind, however, that these promises are in large part premature. The one clearly successful method of treatment by animal tissues is the use of thyroid extracts, and the demonstration of the value of this method was the result of rigorous scientific work extending over more than a decade, and was obtained quite independently of the generalization announced by Brown-Séquard. It seems perfectly certain that whatever else of value may come out of the therapeutical application of tissue extracts must also be established by intelligent scientific research, on the side of experimental as well as clinical medicine, and not by indiscriminate and over-anxious attempts to secure immediate results.

It is my purpose to-day to call your attention briefly to some of the important results obtained by experimental physiology that tend to prove the existence of internal secretions in a number of glandular organs. The main interest to the physiologist lies, perhaps, in the light this work has thrown upon the functions of the blood-glands, or ductless glands, especially the thyroid, suprarenals, hypophysis cerebri, thymus and spleen. Forty years ago the physiology of these bodies was not only unknown, but was beyond the reach of intelligent hypotheses. Within recent years facts have accumulated, especially with regard to the thyroid and suprarenals, that give us a new standpoint from which to view their physiology—a standpoint also from which experimental investigations may be planned with reasonable hope of abundant success in the future. I shall not attempt an historical review of recent work in this subject, as this has been given already in numerous general addresses and special papers.* I desire only to emphasize what seems to be the outcome of the physiological work that has been done in the last twelve or thirteen years, and to explain briefly the character of the work now in progress.

If we include under the term 'thyroid tissue' not only the thyroid body itself, but also the accessory thyroids and the neighboring parathyroids, it has been shown beyond reasonable doubt that complete removal of this tissue in man and the related mammals is followed, as a rule, by serious disturbances of nutrition that are immediately or ultimately fatal to the animal. Moreover, in these cases the reintroduction of thyroid material into the body, whether this introduction be made by grafting the tissue, by subcutaneous or intravascular injections or by absorption from the alimentary canal, results in an amelioration or even entire removal of the symptoms of malnutrition. The physiologists recall with pleasure that these two fundamental facts were first discovered as the result of experimental work in physiology. The effects of complete thyroidectomy were first described by Schiff* in 1856, and the therapeutical use of thyroid tissue arose naturally from the grafting experiments of Schiff† in 1884 and the subsequent experiments of Vassale ‡ and of Gley § upon injections of thyroid extracts. The brilliant results that have followed the use of thyroid tissue in man in cases of myxoedœma, goitre, etc., are, too well known now to require more than a passing reference.

It follows as a logical conclusion from the successful effects attending its therapeutical use, as well as from the evil effects of its destruction or removal, that the thyroid tissue produces, normally, something that is in some way essential to the nutrition of the body. What that something is has been revealed partially by the beautiful chemical and clinical researches of Baumann and Roos. Baumann * has succeeded in isolating a substance, thyro-iodin, or iodothyrin, as it has been named more recently, which, according to the experiments of Roos,† preserves the beneficial effects of thyroid tissue.

The chemical characteristics of this compound will doubtless be presented in Professor Chittenden's paper. It has proved to be a very stable compound, unaffected by boiling, by strong acids and by gastric digestion, and this fact may be taken as a complete disproof of a former view to the effect that the action exerted upon the body by thyroid tissue is due to the presence of special enzymes or ferments. The fact that extracts of thyroid tissue or iodothyrin when absorbed into the blood ameliorate or remove the evil effects resulting from loss of function of the thyroid, seems to prove at once that the normal function of thyroid tissues is not merely to excrete poisonous material from the blood after the manner of the kidneys. It indicates, on the contrary, that these tissues act normally by giving off a material to the blood that in some way affects favorably the nutrition of all or a part of the tissues of the body. In other words, the thyroid tissues form a true internal secretion. Histological research indicates that, so far as the thyroid bodies proper are concerned, this secretion is contained in the so-called colloidal material that accumulates in the interior of the vesicles, and that the mechanism of secretion consists in a rupture of the walls of the vesicles at some point whereby the contents are discharged into the surrounding lymph spaces.*

The most important fact that remains to be discovered is the manner of action of this secretion upon the tissues of the body. At present we can only speculate upon the answer to this problem. More experimental work is required before a definite solution can be reached. To account for the action of the thyroid secretion two main hypotheses have been proposed. According to one hypothesis the function of the secretion is antitoxic. In some way it antagonizes an unknown toxic substance supposed to be formed in the body in the course of normal metabolism. When the thyroid tissues are removed this poisonous material, being imperfectly excreted, accumulates in the blood and produces the fatal symptoms of thyroidectomy by a process of auto-intoxication. The other hypothesis assumes that the secretion of the thyroid acts normally by promoting or regulating the metabolism of other parts of the body, particularly, perhaps, of the nervous tissues. We might designate this as the trophic or neuro-trophic hypothesis. It is less specific than the antitoxic hypothesis, and therefore, perhaps, less objectionable in the present incomplete state of our knowledge; but as no decisive, or even probable, proof can be given for either view, it seems unnecessary to criticise the various facts brought forward in support of one or the other of them. The two great facts to be explained are: first, that complete removal of the thyroid tissues brings on a condition of malnutrition that seems to affect especially the central nervous system; and, second, that injection or ingestion of thyroid ex-

* Baumann: Zeitschrift für physiolog. Chemie, Bd. XXI., 1896; also Bd. XXII.

† Roos: Ibid Bd. XXII.

*Biondi: Berliner klinische Wochenschrift, 1888. Langendorff: Archiv für Physiologie, 1889, Suppl. Bd. Schmid: Archiv für mik. Anatomie, 1896.

tracts while the animal is in this condition restores its metabolism more or less completely to the normal state. While both of these facts are explicable in terms of either of the hypotheses mentioned, the trophic theory does not involve the somewhat strained assumption of an unknown toxic product of metabolism that can not be got rid of completely by the usual methods of excretion.

A very interesting phase of thyroid physiology that has recently come to the front is the nature of the functional relationship between parathyroid tissue and thyroid tissue proper, such as is found in the thyroid body and the accessory thyroids. The parathyroids seem to occur in all mammalia. According to a recent description by Kohn* there is always one of these bodies on each side attached to the external or posterior surface of the lateral lobes of the thyroid, while in some animals, *e. g.*, the dog, cat and rabbit, there is an additional one on each side, imbedded in the substance of the thyroid lobes. Histologically the structure of these small bodies bears no resemblance to that of the thyroid. They possess the general appearance of embryological tissue, and have, therefore, been regarded usually as an immature form of thyroid tissue, which, under the stimulus of increased functional activity, is capable of developing into normal thyroid structure. Satisfactory evidence is lacking that such a transformation does actually take place under the conditions supposed, as, for example, after complete excision of the two thyroid lobes. On the contrary, the evidence from histology, as well as from embryology, seems to indicate that the two tissues are not only fundamentally different in structure, but possibly are also different in origin.

On the physiological side Gley † was the first to prove the great importance of the parathyroids. He showed that in rabbits complete extirpation of the thyroid lobes alone is not followed by a fatal result so long as the parathyroids remain. Removal of both thyroids and parathyroids, however, is in most cases followed by typical symptoms of complete thyroidectomy ending in the death of the animal. This latter result has been contested by some observers, but renewed investigations have demonstrated its accuracy. Gley explained his results on the hypothesis that after removal of the thyroid its function is vicariously assumed by the parathyroids. He concluded, therefore, that the functional value of the two tissues is identical. Recent work, however, tends to throw doubt upon this conclusion. Vassale and Generali * state that in dogs and cats removal of all four parathyroids produces the acute symptoms of complete thyroidectomy, and finally causes the death of the animal, in spite of the fact that the thyroid body proper is left practically uninjured. On the other hand, complete removal of the thyroid lobes is not immediately injurious to the animal, provided the parathyroids—or, in some cases, if even only one of the parathyroids—are left. They contend, therefore, that the result in dogs and cats usually attributed to extirpation of the thyroids is due in reality to the simultaneous removal of the parathyroids.

This result is partly confirmed by the independent experiments of Rouxeau † and of Gley. ‡ The former finds that in rabbits complete removal of the thyroids alone causes no trouble, at least no immediate trouble, while excision of the external parathyroids alone is followed frequently by death, or by convulsive symptoms. Gley

‡ Gley: Ibid.

reports some incomplete experiments upon rabbits and dogs that tend in the same direction. Finally, Moussu,* from experiments made upon mammals and birds, attempts to define in general terms the difference in function between thyroid and parathyroid tissue. According to his experiments, removal of the parathyroids alone is followed by certain acute troubles, such as have been usually described as the result of complete thyroidectomy, while removal of the thyroid lobes alone is followed by chronic troubles of nutrition which he designates as myxoedœmatous or atrophic cretinism. This last result has not been confirmed, so far as I am aware, by others, so that it cannot be accepted with entire confidence. It will be noted, however, that the tendency of this recent work is to show that the functional value of the thyroids and parathyroids is not identical, and that the importance hitherto attributed to the thyroids must be assigned, in part at least, to the parathyroids. The very great interest that these results may have when applied to human pathology and therapeutics will be evident to everyone.

Finally, a word may be said as to the possibility that other tissues exist in the body capable of replacing entirely or in part the functions normally performed by the thyroids or the parathyroids. This possibility seems to be indicated by the fact, commented on by most experimenters in in this field, that occasionally animals are found in which apparently complete removal of all the thyroid tissue, including the parathyroids, is not followed by a fatal result. Such cases may be explained by assuming the existence of accessory thyroids or parathyroids that escape the attention of the operator, but it is also possible that they may be due to the fact that there are other organs in the body that possess a thyroid function. Experiments in this direction have been made upon the spleen and the hypophysis cerebri. With regard to the former organ the results may be considered as entirely negative, while as regards the hypophysis the evidence is unsatisfactory. Some details concerning this last organ will be presented later.

* Moussu: Ibid, Jan. 16, 1897.

The results of recent physiological experiments upon the suprarenal bodies have not been less interesting, although less complete than those upon the thyroid. These curious bodies, like the thyroid, are found constantly in all classes of the vertebrates, and seem, therefore, to be organs of fundamental importance. As long ago as 1856 Brown-Séquard* stated that extirpation of both suprarenals is usually fatal to the animal, death occurring generally very shortly after the operation, more rapidly, according to this observer, than after removal of both kidneys. This statement has been questioned frequently by other observers, but the results of the renewed investigations that have followed upon the recent revival of interest in the physiology of the ductless glands seem to corroborate fully the account given by Brown-Séquard. In the case of dogs, according to Szymonowicz,† death follows the operation within fifteen hours. It has been shown, also, that in some species of animals accessory suprarenals are not uncommon, and it is possible that this fact may explain the survival of a certain number of animals after supposed complete extirpation of the suprarenals. Removal of only one suprarenal does not appear to cause any noticeable trouble. In the case of complete removal, followed by a fatal result, the prominent symptoms preceding death are extreme muscular weakness, asthenia, and, in the case of dogs examined

*Brown-Séquard: Comptes rendus de l'Ac. des Sciences, XLIII., 1856. *Journal de la Physiologie*, I., 1858.

†Szymonowicz: Archiv f. d. gesammte Physiologie, LXIV., 1896.

during this period, a great fall in blood pressure, together with a feeble heart-beat. It will be noted that in cases of Addison's disease in man the important symptoms, in addition to the pigmentation, are also an asthenic condition of the muscles and the heart. What explanation have we to offer for the surprisingly profound effect produced upon the body by the removal of these small organs?

Unquestionably, the most significant facts with regard to this problem have been obtained from a study of the effects of injections of suprarenal extracts into living animals. A number of the earlier experiments of this kind, especially those performed upon rabbits, resulted in the death of the animal, the preceding symptoms being convulsive movements, followed by some paralysis. The really valuable results, however, have been obtained by a more exact study of the effects of such injections upon the vascular and respiratory organs. Most of our knowledge upon these points has been derived from the researches of Oliver and Schäfer,* and Cybulski and Szymonowicz.† These two sets of investigators published their results nearly simultaneously. The important facts determined by them, and since corroborated in many laboratories, are as follows: Extracts of the medulla of the suprarenal bodies injected into the veins of a living animal cause a pronounced slowing of the heart-beat and a large rise of blood pressure. If the animal is first given atropin to paralyze the inhibitory nerves to the heart, or if the vagi are previously cut, the injection causes usually a marked quickening, instead of a slowing of the heart-beat, and a greater, indeed often an extraordinary, rise of blood pressure. The respiratory organs are not affected so seriously, a temporary slowing and shallowing of the respiratory movements being the result usually noticed. The effect upon the heart and blood vessels is quite temporary. Its exact duration depends somewhat upon the dose, and in part upon other less evident conditions, but, as a rule, within a very few minutes the rise in blood pressure, as well as the slowing of the heart-beat, passes off completely. New injections will bring out promptly a return of the effect described, although a continued repetition of the injections at too close intervals results in a progressive diminution of their action. Tying off the kidneys does not appear to prolong the effects of an injection, so that we may conclude that the temporary character of the result produced is not caused by a rapid elimination of the active substance through the kidneys, although, according to Szymonowicz, a part of it, at least, is got rid of by this means. The rapid disappearance, however, of the effects of a maximal or supramaximal dose indicates that the active substance is either quickly destroyed in the tissues or is neutralized in some unknown way.

The physiological explanation of the slowing of the heart caused by the suprarenal extracts offers no difficulties. Since this effect disappears completely upon section of the vagi, or after the injection of a few milligrams of atropin, it can only be due to a stimulating action upon the central endings of the inhibitory fibres, that is, upon the so-called cardio-inhibitory center in the medulla. According to Oliver and Schäfer the inhibitory effect is felt mainly upon the auricles. The beats of this part of the heart become weaker and slower and may cease altogether, while the ventricular beats, although slower, are more vigorous. After the vagi have been cut, suprarenal extracts cause a quicker and, according to Oliver and Schäfer, who measured the extent of

*Oliver and Schäfer: *Journal of Physiology*, XVIII., 1895.

† Cybulski and Szymonowicz: *Gazeta Lekarska*, 1895. (Abstracted in Jahresb. d. Thier-Chimie, 1895. Also Szymonowicz: Archiv. für d. gesammte Physiologie, LXIV., 1896.

the contractions directly, a stronger beat. This accelerating effect upon the heart after removal of the inhibitory fibres is not due, as we might at first suppose, to a stimulation of the central ends of the accelerator fibres, since it is still obtained after section of the cord in the neck, or after extirpation of the first thoracic ganglia. It must, therefore, be due to a peripheral action of the extracts upon the heart itself, either upon the muscle of the heart directly (Oliver and Schäfer) or upon the so-called motor ganglia (Szymonowicz, Gottlieb).

The effect of the injections upon blood pressure has been explained differently by those engaged in the work. Both Oliver and Schäfer, and Cybulski and Szymonowicz, believe that the enormous rise in blood pressure is due mainly to a great constriction of the arterioles. According to the latter this constriction is brought about by a stimulating action of the extracts upon the vaso-motor centers in the medulla and cord, while according to Oliver and Schäfer the action is exerted directly on the muscles of the blood vessels. Szymonowicz admits that if the cord is cut just below the medulla a great rise of pressure can still be obtained, but he explains this by supposing that the extract acts on the spinal centers. He asserts that if the entire cord is destroyed a rise of pressure can no longer be obtained. The experiment that he gives to illustrate this last point is, however, far from being convincing. The protocol of the experiment shows that the act of destroying the cord in itself reduced the blood pressure to zero. Moreover Biedl* reports that he has been able to get a rise in pressure from injection of the extracts after complete extirpation of the cord. The evidence, therefore, seems to favor the view proposed by Oliver and Schäfer, and this view is still further supported by the fact that when the volume of a limb is measured plethysmographically it often shows a distinct diminution after suprarenal injection, even though its nervous connections with the central nervous system are entirely severed.

*Biedl: Wien. klin. Wochenschrift, IX., 1896.

There are, however, some facts reported in the experiments made by different observers which indicate that the assumed action of the substance on the peripheral arteries does not alone account for all the changes produced in blood pressure. It is probable that the greater force of the heart-beat plays an important part, as Gottlieb* contends, in causing the increase of arterial tension. Thus Szymonowicz reports measurements of the pressure in the external jugular vein made during one of his experiments. According to this report the venous pressure rose and fell with the arterial pressure, which is not what one would expect to occur in the case of a general constriction affecting the arterioles alone. According to Bayliss and Hill,† also, the general venous pressure increases with the rise in arterial pressure. So in a number of the published tracings given by Oliver and Schäffer it appears that the vaso-constriction was more pronounced in the abdominal viscera than in the limbs, since the volume of the latter measured plethysmographically showed an increase of a passive character, apparently, while the volume of the kidney or spleen was greatly diminished.

The significance of the marked reaction exhibited by suprarenal extracts depends very largely upon the possibility of proving that the substance producing the reaction is formed normally within the gland. It is conceivable, of course, that in the dead gland post-mortem changes might cause the formation of a substance giving this reaction, although under the normal condi-

* Gottlieb: Archiv f. exper. Pathologie u. Pharmakologie, XXXVIII., 1897.

† Bayliss and Hill: *Journal of Physiolology*, XVIII. p 352, 1895.

tions of life it might not exist. Fortunately, we have direct proof that the active substance in question is a normal product of the metabolism in the gland. Cybulski and Szymonowicz found that blood drawn from the suprarenal vein, when injected into the circulation of a normal animal, gives the same effect, although less in amount, as extracts of the suprarenal glands, while blood from other veins has no such action. This result has been denied by Oliver and Schäfer, apparently upon insufficient experimental grounds. Langlois,* on the contrary, has been able to corroborate this effect of suprarenal blood, and, in the laboratory at Baltimore, Dr. Dreyer has obtained clear proof of a similar action. It appears from Dreyer's experiments that the effect is not obtained in every animal, but in some cases the results are very positive, and in a matter of this kind the positive evidence is the most important. When we remember that we are dealing most probably with a material formed by the secretory activity of gland cells, and that the amount of this material may vary at different times or under different circumstances, it is not surprising that negative as well as positive results are obtained.

Since it seems certain that the substance does occur under normal conditions in the venous blood flowing from the gland, we are justified in concluding that it is a normal product of the metabolism of the medullary cells of the gland, and that it is discharged or secreted directly into the blood. It must, therefore, exert continually a stimulating effect upon the heart and blood vessels. In corroboration of this last conclusion we have some striking experiments recorded by Szymonowicz which show that after complete extirpation of the two glands the blood pressure becomes greatly depressed. Both Oliver and Schäfer, and Cybulski and Szymonowicz, conclude that the normal function of the suprarenals consists in furnishing this stimulating substance to the blood. The former observers believe that its effect is mainly upon the muscular tissue; that it has a general tonic or augmenting action on all varieties of muscle found in the body—the striated muscle as well as the cardiac and plain muscle tissue. Cybulski and Szymonowicz hold essentially the same general view, except that they believe that the substance acts upon the nerve centers controlling the muscular tissues rather than on these tissues directly. It is, perhaps, impossible at present to decide as to this detail. Oliver and Schäfer have shown, without much doubt, that the substance acts upon the blood vessels after their connections with the central nervous system have been completely severed, and, on the other hand, there is clear proof that it affects at least one part of the central nervous system, namely, the cardio-inhibitory center. Further experimenting will probably soon furnish more definite information upon the extent to which the muscular and the nervous tissues are affected by this substance. Upon either of the views proposed we can understand at once why removal of the suprarenals brings on a condition of muscular asthenia, and why the continual activity of these organs is so essential to the body as a whole. It is significant, in this connection, to recall that Oliver and Schäfer found that extracts of the suprarenals in cases of Addison's disease did not contain this stimulating substance. The hypothesis that the suprarenals secrete a stimulating substance that augments the tone of the muscular system, either directly or indirectly, is not the only one offered to explain the physiology of these bodies. According to some observers the main function of the suprarenals, like that of the thyroids, is to produce an anti-

* Langlois: Archives de Physiologie normale et pathologique, 152, 1897.

toxic secretion capable of neutralizing or destroying certain poisonous products of body metabolism. The toxic products in this case have been supposed to originate in the functional metabolism of muscular tissue, and the asthenic condition following upon extirpation of the suprarenals has been compared with the similar effect produced by injecting the extracts of fatigued muscles into the circulation. The main argument of those who hold to this view seems to rest upon the fact that the blood of an animal that has been deprived of its suprarenals and is beginning to show the typical effects has a toxic effect when injected into the circulation of another animal from which the suprarenals have been removed shortly before. The fatal symptoms are brought on by the injection more rapidly than would happen otherwise. One cannot feel a great deal of confidence in this argument as contrasted with the apparently direct evidence offered in favor of the stimulation hypothesis.

Unfortunately, the physiological evidence with regard to the importance of the suprarenals to the body has not found so satisfactory an application in practical medicine as in the case of the thyroids. Suprarenal extracts and tissue have been used in cases of Addison's disease, but the beneficial effects obtained have not been so clear as in the case of thyroid extracts. Some of the results reported, however, indicate that the method is at least a hopeful one in certain cases.

A third interesting member of the group of ductless glands is the hypophysis cerebri, and a few words may be said as to its supposed physiological activity. This gland is commonly described as consisting of two parts, the anterior and the posterior lobe. The histology and the embryology of the two parts indicate that they are entirely different in origin and in structure. The anterior lobe is evidently a glandular structure. It develops originally as a saccular invagination from the buccal epithelium, and has essentially the same origin in all the vertebrates that have been examined. According to Haller* it is not strictly a ductless gland, since it possesses an imperfectly developed system of ducts that opens between the dura and the pia mater. It is evidently a secreting structure, and the fact that its secretion is discharged between the meningeal membranes suggests some special connection with the physiology of the brain. Histologically its structure recalls that of the thyroid gland, particularly in the fact that a colloidal material is said to occur frequently in the lumina of the gland tubules. In some animals, *e. g.*, the dog and the cat, it is a very small body, but in others, as the rabbit, sheep, ox and man, it is of considerable size and bears every indication in its structure of being an active secretory organ.

The posterior lobe, on the contrary, is very small in all animals and has the appearance of being a rudimentary organ. It develops as an outgrowth from the infundibulum of the brain and is more properly spoken of as the infundibular lobe. Its histology is very incompletely known. According to Berkley† it contains numerous typical nerve-cells, ependymal cells and neuroglia, a number of glandular epithelial cells arranged in part to form tubes or closed vesicles that contain a colloidal material, and some curious structures resembling nerve and organs.

The observations bearing upon the functions of the hypophysis have been limited to the glandular lobe. On the pathological side it has been shown that in many, if not in most, of the cases of acromegalia the glandular lobe exhibits pathological changes. For this reason extracts of the gland have been

* Morphologisches Jahrbuch, XXV., 1896.

† Berkley: The Johns Hopkins Hospital Reports, IV., 1895.

used therapeutically in cases of acromegalia, and, according to some reports, benefits have followed the treatment to the extent that some of the disagreeable features have shown amelioration. The evidence from this side, however, is not satisfactory, and the nature of the connection between acromegalia and disturbance of the function of hypophysis, if any exists, needs more complete investigation.

The experiments made by the physiologists are also meagre and inconclusive. Gley* reports a set of experiments made upon rabbits, in which he attempted to destroy the gland by an operation from above. The experiments were made upon rabbits from which the thyroid lobes had been removed previously, with the idea of demonstrating that a similarity in function exists between the thyroid and hypophysis. All but one of the animals died, owing to the severity of the operation. In the single survivor it was noted that the animal exhibited at times spasmodic muscular contractions and some degree of paresis, and that it died about a year after the operation. On the assumption that the animal would have lived if the thyroid lobes alone had been removed, Gley concluded that the removal of the hypophysis had prevented the parathyroids from replacing completely the loss of the thyroid, and that, therefore, the hypophysis is related in function to the thyroid tissue. Naturally but little importance can be attached to a single experiment of this kind, and, so far as I know, the author has not repeated the investigation. Vassale and Sacchi† claim to have removed the hypophysis partially or completely in a number of animals by an operation through the base of the skull. In cases of complete removal the animal died within a short time—fourteen days or less—after exhibiting a number of symptoms similar to those caused by thyroidectomy, such as muscular tremors and spasms and the development of a cachectic condition. Most physiologists, I fancy, will accept these experiments also with some hesitation until they have been confirmed by other observers. The very severe character of the operation necessary to reach the gland makes it questionable whether the results reported were due to its removal alone, although the experiments were evidently made with great care.

*Gley: Archives de Physiologie normale et pathologique, 1892, 311.

†Vassale and Sacchi: Archives ital. de Biologie, XXII., CXXXIII., 1895; also XVIII., 1893.

Szymonowicz and also Oliver and Schäfer report experiments upon the effects of injections of extracts of hypophysis into the circulation of normal animals. Szymonowicz states that in two experiments he obtained a slight fall pressure and a quickening of the heart-beat. He concludes, therefore, that the physiological action of these extracts is opposed to that caused by extracts of the suprarenals. Oliver and Schäfer, on the contrary, report that extracts of hypophysis exert an effect very similar in some ways to that shown by suprarenal extracts. For instance, they cause a marked rise of blood pressure, together with an augmentation of the heart-beat. Unlike the suprarenal extracts, however, they do not produce a slowing of the heart-rate when the vagi are intact. Upon the basis of these incomplete experiments they draw the somewhat hasty conclusion that the hypophysis and the thyroid are not similar in function, and that the hypophysis is not capable of assuming vicariously the activities of the thyroid.

I have recently made a number of experiments upon this organ, the results of which have been quite uniform and in many respects very different from those obtained by the authors just quoted. My experiments were made with the hypophysis of sheep mainly, although at first the gland of the dog was also used. The extracts were

made in normal saline, or in glycerine followed by dilution with normal saline, and usually the fresh gland was employed. The experiments differed from those reported by others, in that extracts were made separately of the glandular and the infundibular lobe, and the physiological effects of each were tested by injection into the circulation of normal dogs. It was found that the extracts of the glandular lobe have little or no perceptible effect when injected alone. Extracts of the small infundibular lobe, on the contrary, have a distinct and remarkable effect upon the heart-rate and blood pressure, an effect which resembles in some respects and differs in others from that shown by suprarenal extracts.

Briefly stated, these extracts injected into the normal animal with its vagi intact cause a very pronounced slowing of the heart-beat, similar to that caused by suprarenal extracts, but lasting a much longer time. The heart-beat is not only slowed, but is considerably augmented in force, as is shown by tracings taken with a Hürthle manometer. At the same time the blood pressure rises to a considerable extent, owing, apparently, to a peripheral constriction of the blood vessels, since oncometric tracings from the kidney show that this organ shrinks greatly in volume. Usually the constriction of the blood vessels occurs first, so that the pressure rises for about 20 mms. or more more of mercury. This is succeeded sometimes by a temporary fall of pressure during which the heart-rate may be increased, and then the slowing of the heart begins, while the pressure rises again to a greater or less extent above the normal. This last effect continues for a relatively long time and passes off gradually. The slowing of the heart may continue for half an hour or longer. If the dose used is a maximal one, and a second injection is given too quickly afterward, little or no effect is obtained. If, however, the dose is not too strong, and sufficient time is given given for its action to wear of, a repetition of the effects is obtained, and this may occur a number of times, although the effects decrease progressively in intensity.

The effects of the injection are somewhat different if the vagi are previously cut, or if a little atropin is given to paralyze the inhibitory fibres. Under these circumstances the slowing of the heart-rate is very much less marked, although not entirely lacking. In round numbers it may be said that with the vagi intact the heart-rate is reduced about 50 per cent., while in the atropinized animal the reduction is about 20 per cent. It might be added that an animal deeply under ether alone behaves in this respect like an animal with its vagi cut. This result indicates that the slowing of the heart-rate in the normal animal is due in part, but only in part, to a direct action on the medullary centers of the inhibitory fibres. On the other hand, the rise of blood pressure after section of the vagi is greater. Usually the blood pressure rises rapidly for about 20 mms. of mercury; this is succeeded in some cases by a temporary fall, and then the pressure again rises rapidly, reaching a height, in some cases, nearly equal to that caused by suprarenal extracts. During this last phase the heart-beats are slower and more powerful, the effect in this respect differing from that caused by suprarenal extracts. The effect lasts longer than with suprarenal extracts, and a longer interval must be allowed before a new injection will give the same result. I have obtained a marked rise of pressure from injection of extracts of the infundibular lobe, after severance of the cord below the medulla, and in one case after removal of most of the thoracic part of the spinal cord in addition, thus indicating that the constriction of the blood vessels is probably a peripheral effect, and not due to

stimulation of the vaso-motor centers. These observations that I present here only incompletely may be taken to indicate that the infundibular lobe of the hypophysis is, in all probability, not a rudimentary organ, but a structure that has some important physiological activity. Moreover, its function is probably different from that of the glandular lobe, and possibly quite independent of it. With regard to the function of the glandular lobe, the method of injecting extracts into the circulation of a normal animal seems to teach us nothing. While the negative results thus obtained do not oppose, they cannot be said to support, the favorite hypothesis that this part of the hypophsis cerebri has a function resembling that of the thyroid lobes. I venture to suggest that this supposed similarity in function might be tested most satisfactorily upon human beings by feeding the gland in cases of myxoedœma or goitre and ascertaining whether a reaction similar to that caused by the thyroid can be obtained.

W. H. HOWELL.
JOHNS HOPKINS UNIVERSITY.

*ON THE RELATIVE VARIATION AND CORRELATION IN CIVILIZED AND UNCIVILIZED RACES.**

THE general conclusion would then be that, with increased civilization, absolute size† and variation tend to increase, while correlation, to judge by the males, is stationary; to judge by the females, tends to increase.

It will be found somewhat difficult to reconcile these results with any simple applications of the principle of natural selection. In the first place increased variation undoubtedly suggests a lessening of the struggle for existence, and there can be no question that this increase has gone on among civilized races (See 'Variation in Man and Woman'). The lessening of the struggle has probably been greater for woman than man; hence the principle of natural selection might help to explain the preponderance of variability in civilized woman. The increase in size with civilization seems, on the average, also incontestable. But is it the effect of lessening the struggle for existence? The possibilities may, perhaps, be summed up as follows:

(*a*) The civilized races may have survived owing to their superior size. It may be a result of the struggle in the past. To this must be objected that the increase of size appears to be a progressive change still going on, and yet increase of variation should show a lessening struggle for existence.

(*b*) The effect of suspending natural selection may be to increase size. This would be a blow for panmixia, for we might naturally have expected a regression to the smallness of the more primitive races. It would leave unexplained the apparently smaller progress of women as compared with men, for in their case we might argue from the variation that the struggle for existence is relatively less than in the case of man.

(*c*) The larger size of the civilized races may be due to better food supply and better physical training; in short, it may be due, not to evolution, but to better conditions of growth. This hypothesis does not involve the assumption that acquired characters are inherited. Diminish the food supply and abolish physical training, and the size would sink to the level at which natural selection had left it. Physical

* Conclusion of a communication made to the Royal Society.

† This is only *generally* true, not in every individual case. The French femur is longer than that of the Aino, of neolithic man, and of the ancient inhabitants of the Canary Islands. On the other hand, the French femur appears to be slightly less than the Libyan, although the humerus is somewhat greater. The French women appear in all long bones less than the Libyan women.

training in civilized races being usually more adequate in the case of man than of woman would, perhaps, explain why man has progressed more rapidly in size than woman. It seems impossible, taking variation as a measure of the intensity of selection, to reconcile the relative increases in size of man and woman with any direct effect of natural selection.

8. To sum up, then, the following results seem *suggested* by these measurements.

(i.) Civilized man has progressed generally on primitive man in size, variation and correlation.

(ii.) This progression can hardly be accounted for by increassd selection (because of the increased variation), not by decreased selection (because it is inconsistent with the relative changes in male and female size). It might possibly be accounted for by decreased selection and improved physical conditions.

(iii.) Woman is more variable than man in civilized races.

(iv.) Woman is more highly correlated than man in civilized races.

(v.) In uncivilized races the sexes are more nearly equal in the matter of size, variation and correlation than in the case of civilized races.

(vi.) It is impossible to say that civilized woman is nearer to the primitive type than civilized man, for while civilized man differs more from the primitive type than civilized woman, so far, probably, as absolute size is concerned, he has made only about half her progress in variation, and hardly any progress at all in correlation.

(vii) The causes (*e. g.*, lessening of selection) which tend to increase variation may also increase correlation. In other words, the intensity of the struggle for existence is not necessarily a measure of the intensity of correlation.*

The measurements made by Mr. Warren on the Libyans, the results of which he has kindly favored us with, are, on the whole, fairly in accordance with the above conclusions. He finds for the

Mean of the sexual ratio of the means..............1.092
" " " the variations.........1.028
" " " the correlations.......1.068

The corresponding quantities for the French are: 1·109, 0·939, 0·956, or, we concluded, that in passing from uncivilized to civilized peoples, from Libyan to French, the men gain on the women in size—here very slightly, and the women gain upon the men very markedly in variation and correlation.

These results are merely suggestions, but they may possibly serve to emphasize the importance of a careful measurement of the long bones of, say, 100 members of both sexes for a series of civilized and uncivilized races. In the former case at least there does not appear to be any real difficulty, except the need of coöperation, in obtaining measurements similar to those of M. Rollet, for both English and Germans. The value of such statistics for comparative purposes would be very great.

ALICE LEE,
KARL PEARSON.

* The mathematical theory of selective correlation shows that the close selection of an organ, say the femur, may actually tend to reduce the correlation between two other organs, say the humerus and the radius.

MIGRATION OF THINGS AND OF MEMORIES.

IN the minds of some students the question of migration of forms is frequently confounded with that of the migration of tribes. It must not be forgotten by those who are carefully studying the origin of industrial forms on the Western World that there were daily mails delivered on the American shore from the Eastern Continent, from the remotest antiquity.

The United States Navy has been dropping bottles overboard in the Atlantic

Ocean, at the Azores, in deep water along the coast of Spain and from the Madeira and the Canaries southward along the coast of Africa. All of these bottles that have been recovered have been found on the coast of South America, on the Antilles, and some of them as far west as the mouth of the Rio Grande. It can be inferred from this therefore, that every buoyant object which has been dropped into the ocean during the present geological epoch by prehistoric or historic Spaniards, Portuguese or Africans has found its way to America and been stranded somewhere between the 10th parallel south and the 30th parallel north.

In the northern part of the Atlantic Ocean the currents run the other way and the mails have been delivered from America to Europe. In the Pacific Ocean the daily mails delivered on the west coast of America from Mount Saint Elias southward have proceeded from about the 20th parallel north, in the vicinity of the Malay Peninsula and Archipelago, thence have travelled through the China Sea and the Japanese Sea to pick up objects designed for the Western Hemisphere.

In the Southern Hemisphere the mails travel the other way and materials consigned to the Ocean Current Company were taken from Chili and Peru to be delivered upon the Easter Island and the various groups of Polynesia, some of them reaching as far as Melanesia. In addition to these great mail services of the Pacific there was a narrow strip of service called the 'counter-current' between the equator and the 10th parallel north, the articles consigned to it being delivered on the west coast of Central America.

In the Arctic Ocean the mails proceeded from west to east, passing up through Bering Strait, across the Pole, and finding their way first to east Greenland and then around Cape Farewell to the southwestern shores of that great island. The Arctic current from Baffin Land and northward brought the mails from the Eskimo area southward even as far as Charleston, South Carolina. The consequence of such uninterrupted communication cannot be overestimated. All who have studied the arts of primitive races know how quickly their plastic minds respond to a congenial suggestion. It would not even be necessary for a Chinese or Japanese vessel to bring a single living teacher to take part in the pedagogic work of instructing the West Coast tribes in eastern Asiatic arts.

The recent example of a throwing stick which drifted from Port Clarence, south of Bering Strait, and was picked up on the shores of west Greenland by Dr. Rink, is one of an interrupted series of communications between one of those great mailing stations and another. A second element in technical pedagogy has not been emphasized by any modern writer, and yet it cannot be overlooked; and that is the survival of industrial processes and productions in the myths and traditions of wandering tribes, so that one of them having passed over a long area where a certain kind of activity was not demanded, and coming again to a place where the conditions are favorable to its revival, changed a song or an ancient tribal memory into an actual fact again.

O. T. MASON.

FIELD WORK OF THE UNITED STATES GEOLOGICAL SURVEY.

THE plans of operation of the United States Geological Survey for the fiscal year 1897–1898 have been approved by the Secretary of the Interior and the work of the field season of 1897 has been started, the parties having all taken the field. The sums appropriated for the Survey this year were given in detail in a recent issue of SCIENCE, separate amounts being set apart for specific branches of work and for the

salaries of persons connected with these branches, making the aggregate amount for the Geological Survey for the fiscal year 1897–'98 $967,840, a decided increase, though the additional sum does not go to the geologic branch.

For convenience in administration the work of the Survey is divided into four branches, each of which is again separated into a number of divisions. The branches are geology, topography, publication and administration; geology and topography being the main branches.

In geology the field work extends all over the United States from New England to the Pacific. Professor N. S. Shaler, of Harvard University, is at the head of a party which will continue the work begun last year of the survey of the Richmond coal basin of Virginia. Professor Walcott says in his report: "Although these Virginian fields are apparently remote from the New England region, the geologic problems are closely related to those which Professor Shaler has particularly studied, and it is convenient to continue the work under his direction." Professor Shaler has already completed the study of the Narragansett coal basin in Massachusetts and Rhode Island, and the publication of results has been begun; and a report on the Cape Cod geology is also proposed for publication.

A party under Professor Emerson is continuing his work of the last six years in studying the crystalline schists in eastern Massachusetts, and one under Professor T. Nelson Dale, in cooperation with Professor Wolff, will extend the work of previous years north and east to cover the area of the Bennington (Vt.) quadrangle. The study of the roofing-slate belt of New York and Vermont has been completed. Professor Kemp, of Columbia University, goes to the southeastern Adirondack area to work on the mapping of that section.

Professor J. E. Wolff will make a special study of the crystalline rocks of northern New Jersey, including zinc and iron ore deposits. He will also complete the survey of the Franklin (N. J.) quadrangle. He will also assist Professor Dale, as above mentioned. Mr. David White will study the coal deposits of Ohio, Pennsylvania, Virginia, West Virginia and Tennessee, from a paleobotanic standpoint, and Mr. M. R. Campbell will continue the study of the distribution of the coals of West Virginia and Kentucky. Mr. J. A. Taff will inaugurate work in the coal fields of Indian Territory. Dr. C. Willard Hayes' work in the southern Appalachian province has been brought to such a stage of development that he will prepare a monographic report upon it. Mr. Arthur Keith will continue the mapping of the crystalline rock areas in which he has been engaged, extending from the northern line of Maryland to North Carolina. His work is directed to an elucidation of the obscure geologic relations of the rocks of the Blue Ridge and Piedmont Plateau and their bearing upon geologic history.

Two parties will be sent to the Coastal plain region. One, under Dr. William B. Clark, of Johns Hopkins, will study the Cretaceous formations, which include the marl and clay beds of Maryland and New Jersey, and one under Mr. George H. Eldridge, who has been working for the past year on his report of the phosphate deposits of Florida, will spend the summer in the Atlantic Coast plain region.

Seven parties have been sent to the interior Mississippi region, and five to the Rocky Mountain region which lies between the British and Mexican boundaries on the north and south, the margin of the great plains on the east, and, approximately, the line of the 119th meridian on the west, and embraces the Rocky Mountains and their foothills. Mr. Arnold Hague is in charge

of one of these parties, which will do the field work necessary to enable him to complete his monograph on the Yellowstone National Park. This was interrupted by his work on the Forestry Commission of the National Academy of Sciences last year. Professor Hague will survey the Absaroka Range, one of the most rugged and inaccessible of the Rocky Mountains. Dr. W. H. Weed will continue the study of ore problems, etc., in Montana.

Mr. S. F. Emmons will be in Europe the greater part of the season, but under his direction surveys of the Tintic mining district of Utah will go on.

The Pacific region is covered by five parties, but the appropriation of $5,000 made for work in Alaska was not passed in in time to be available during the present year.

The paleontologic work is to be continued on the same lines as during the last year. "Special attention," says Professor Walcott, "will be given to the identification of certain fauna and flora in the coal regions of the Appalachians and the Rocky Mountains, and a thorough study will be made of the Cretaceous fauna of Colorado, Texas and Kansas, and the Tertiary fauna of California and Oregon, with relation to areal and vertical distribution, for the purpose of aiding the geologist in the solution of problems in areal geology. This will require that several members of the paleontological force shall continue field work, either independently or in connection with geologic parties."

It is also proposed to continue the collection and publication of data touching the mineral resources of the United States. Dr. D. T. Day has direction of this work, and $20,000 has been specifically appropriated for it.

One hundred and seventy-five thousand dollars has been allotted for topographic surveys proper and $150,000 for forestry surveys, and the plan of work will not be changed in character and organization from that of last year, except that additional work is imposed by the survey of the forest reserves.

The work of subdivision and topographic mapping in the Indian Territory is continued under C. H. Fitch, with the same organization as last year. Mr. Fitch expects to complete his field work by December 1st, with the exception of the resurvey of the Chickasaw Nation, for which $141,500 has been especially provided.

THE PHYSICAL SOCIETY OF LONDON.

THE Physical Society of London (or, as it is more generally called, the Physical Society) was founded in 1874 and was the outcome of a movement set on foot by the late Professor Frederick Guthrie, at that time professor of physics in the institution now known as the Royal College of Science. Among the original members of the Society were Professor W. G. Adams, Dr. Edmund Atkinson, Mr. Crookes, Professor Carey Foster, Dr. Gladstone, Professor Guthrie, Mr. Haddon, Professor John Perry, Professor A. W. Reinold and Professor Tyndall.

The purposes of the foundation were the receiving and discussing communications relative to physics, the exhibition of apparatus for physical research and of experiments illustrating physical phenomena and the publication of communications made directly to the Society and of other papers relating to physics.

Through his official connection with the Royal College of Science, Professor Guthrie was able to secure the consent of the Lords of the Committee of Council on Education, who are the authorities having jurisdiction in the matter, to the meetings of the Society being held in the physics lecture room of the College of Science and to the use of the physical laboratory and apparatus of the

College for the experimental illustration of papers read. The Society was thus relieved of all charges for rent of its meeting room and was consequently able to carry on its work without charging a larger subscription than one pound a year, or a single payment of ten pounds as a life composition for annual payments, with an entrance fee of one pound.

On this slender financial basis a very large amount of good work was done. Not merely were Proceedings issued containing the papers which had been presented to and accepted by the Society, but the works of Joule and of Wheatstone were printed in extenso and distributed to the members. Similarly were published in English Helmholtz's Memoir 'On the Chemical Relation of Electrical Currents,' Hittorf's Memoirs 'On the Conduction of Electricity in Gases,' Puluj's Memoir on 'Radiant Electrode Matter' and Van der Waal's Memoir 'On the Continuity of the Liquid and Gaseous States of Matter;' a useful work of reference by Mr. Lehfeldt entitled 'A List of the Chief Memoirs on Physics of Matter' and a table of 'Hyperbolic Sines and Cosines' by T. H. Blakesley.

The founders of the Society purposely avoided setting up a new journal, being of the opinion that the unnecessary multiplication of the sources to be consulted in search of scientific facts was a thing to be avoided. By an agreement with the proprietors of the *Philosophical Magazine* it was arranged that such of the papers read before the Society as the Council might decide to publish should, in the first instance, be printed in that magazine, and afterwards collected and issued to the members of the Society in the form of Proceedings. A large circulation was thus at once secured and the creation of an an additional physical journal avoided.

As the Society grew it became desirable that it should have a local habitation not far from the other leading scientific societies of London, and the Council were fortunately able to make arrangements with the Chemical Society, whereby since 1894 the meetings have been held in the rooms of the latter Society in Burlington House.

In 1895 the Proceedings of the Physical Society, which had hitherto appeared at irregular intervals, began to be published in monthly parts, and at the same time the Society began the publication of Systematic Abstracts of papers in Physics printed in foreign journals. It is hoped that these Abstracts will be of great use in facilitating a knowledge by English-speaking physicists of the work which is being done by their colleagues in other countries. The increased activity of the Society has involved an increase of expenditure, and to meet this it has been necessary to raise the subscription payable by members. At the present time the annual subscription is £2 and 2s.

The number of members is over 400 and and the list includes nearly all the leading physicists of the United Kingdom.

The Regulations of the Society provide for the election of a limited number of foreigners as honorary members, and in this way some of the most distinguished physicists in many countries are connected with the Society.

CURRENT NOTES ON ANTHROPOLOGY.

THE NATIVES OF THE PHILIPPINES.

It is well known that the Philippine Islands had when first discovered by Europeans two quite different classes of population. On the coast was a light colored race similar to the Malayo-Polynesians and speaking an allied dialect. In the interior was a small-sized, black race, called by the navigators 'Negritos.' In the Proceedings of the Prussian Academy of Sciences, 1897, No. XVI., Professor Virchow figures and describes a large deformed skull from a cave in the Archipelago, which, in its antiquity

and similarity to some others exhumed on other islands, suggests the probability that it comes from a prehistoric race, older than either of those mentioned, and perhaps not belonging among the Malayan stock.

With regard to the Negritos, Professor Virchow expresses the opinion that they are a 'primitive' type; at the same time he throws out various speculations on the rapidity and uncertain limits of variation in man, how much it arises from environment, etc, so that the reader almost expects him to say that originally the two types of the Philippines might have been one.

It should always be remembered that the so-called 'Law of Variation' in organic forms is a purely negative expression, formulating merely non-identity, and can have no other limits than those temporarily established by observation.

WAMPUM AND STONE MASKS.

PROFESSOR E. T. HAMY, well known for his numerous American studies, and now President of the Society of Americanists of Paris, has lately published two articles in the journal of the Society of considerable interest.

One is a description of a wampum belt believed to be of Huron manufacture, transferred, it is suggested, at the treaty made by Frontenac in 1673. A full examination of the beads and the method of boring would be desirable, in order to ascertain its antiquity.

The second paper is on a stone mask brought by M. Pinart from the Northwest coast. Its traits are allied to those of the wooden mask, but as an example in stone from that locality it is believed to be unique.

Another subject, to which Professor Hamy has devoted a short article in the *Compte Rendu de l'Academie des Inscriptions*, is a series of six ancient portraits of the Incas of Peru, of unknown provenance, discovered in an old house at Rochefort. They are especially interesting as showing the sumptuous official costume worn by the ancient monarchs of the Quichuas.

NATIVE AMERICAN ART-MOTIVES.

DR. H. STOLPE, of the Stockholm museum, Sweden, who probably stands at the head of European students of aboriginal art, has lately published an elaborately illustrated folio entitled 'Studies in American Ornamentation,' of which there is an extended notice in *Globus.*

He examines with patient care the art-motives of a number of tribes of North and South America. His investigations show that in nearly all examples the oldest decoration was anthropomorphic or zoomorphic. Emblems of the wind, the water, etc., also occur. A certain number are figured of which the interpretation is obscure.

Dr. Stolpe is severe on Hamy, Schurz and other modern writers who, in the face of well-known principles of scientific investigation, spend their time in seeking out analogies with the Old World in ancient American art. He has not found a trace of such cultural connection, and declares that wherever the material has been abundant all native American art-development can be proved to have been indigenous.

It is to be hoped that this work, which is in Swedish, will soon be translated into English.

D. G. BRINTON.
UNIVERSITY OF PENNSYLVANIA.

NOTES ON INORGANIC CHEMISTRY.

As briefly noted in SCIENCE, fluorin has been at last liquefied. Professor Moissan, of Paris, brought all his apparatus for the production of fluorin to the Royal Institution, where he could avail himself of the

unrivalled appliances for the production of intense cold, as well as of the assistance of Professor Dewar. An account of the experiments is given in the *Comptes Rendus*, and with notes by Professor Crookes in the *Chemical News* of June 11th. The difficulties encountered in the liquefaction of fluorin are its intensely corrosive action and its very low temperature. Several liters of liquid oxygen, the refrigerant, were used in the research. Happily, at very low temperatures fluorin loses much of its chemical activity, no longer attacking glass. Fluorin becomes liquid at —185° C., is clear yellow and possesses great mobility. At this low temperature silicon, carbon, sulfur, phosphorus and reduced iron previously cooled in liquid oxygen and then placed in an atmosphere of fluorin, do not become incandescent, and the iodin of potassium iodid is not displaced by fluorin. Benzene and turpentine are, however, decomposed with incandescence when the temperature rises to —180 C., showing the great affinity of fluorin for hydrogen. Note is made of the fact that when fluorin is passed through liquid oxygen a white flocculent precipitate is formed, which when filtered off deflagrates with great violence as soon as the temperature rises. It would seem to be a compound of fluorin and oxygen, and is being further investigated.

In a recent *Comptes Rendus*, Berthelot and Vieille give an account of further investigations on the dangers attending the storage of acetylene. They had previously shown that, if under less than two atmospheres pressure, acetylene cannot be detonated by fulminates or by red-hot wire. They now show that acetone is a good solvent for acetylene. While such a solution is still capable of explosion, it is much safer than the gas alone, and the pressure at which an explosion is possible is raised from two to ten kilograms per square centimeter. In a large vessel the amount of acetylene that can be safely stored is fifty times greater with the acetone than without it.

At the conference of the Institution of Civil Engineers, held in London the last of May, Professor Biles read a paper before the Shipbuilding Section on 'Improved Materials of Construction.' In the course of the discussion which followed it was strongly brought out that nickel steel is the coming material for ship building, provided its cost can be made satisfactory. For this, it was said that new deposits of nickel must be discovered and the cost of its metallurgy must be reduced.

The *Engineering and Mining Journal* gives a report of the Carborundum Company for 1896, by which it appears that the output of crystalline carborundum for last year was nearly six hundred tons. It seems probable that the amorphous carborundum formed in the manufacture, which has heretofore had no use, will ultimately displace ferro-silicon in the manufacture of steel. Germany alone would use 2,500 tons of carborundum annually if it could be furnished at not over six cents a pound, and the Carborundum Company claims it can do this.

J. L. H.

SCIENTIFIC NOTES AND NEWS.

We are informed that the preliminary programs for the meetings of the sections of the American Association for the Advancement of Science promise many interesting papers and a large attendance. No less than twenty-five papers have already been entered to be read before the physical section, including contributions from a number of leading physicists, and other sciences will be equally well represented. We hope to publish in advance of the meeting the full programs for all the sections.

The fourth summer meeting of the American Mathematical Society will be held, as we have already announced, at Toronto, Canada, on Monday and Tuesday, August 16th and 17th.

It will thus immediately follow the adjournment of the American Association for the Advancement of Science from Detroit to Toronto, and immediately precede the opening of the Toronto meeting of the British Association for the Advancement of Science. The committee of arrangements announce that by invitation of the University of Toronto the Society will meet in the main building of the University. The Society will be called to order by the President, Professor Simon Newcomb, on Monday morning at 10 o'clock, and the Council will meet Monday evening. The committee has decided to set apart one of the sessions during the meeting for the general discussion of the following subjects: (1) The accurate definition of the subject-matter mathematics. (2). The vocabulary of mathematics. The possibility of correcting and enriching it by cooperative action. In connection with the former of the subjects, reference may be made to the Presidential address of Mr. A. B. Kempe before the London Mathematical Society (Proceedings of the London Mathematical Society, Vol. 26, pp. 5–15). No special railroad rates to and from this meeting have been secured, but members are entitled to special rates for the numerous excursions arranged in connection with the meeting of the British Association. Members may join the British Association on payment of five dollars. Members of the American or of the British Association secure reduced rates to and from the meeting through those bodies.

Mr. C. L. Marlatt, Secretary of the Association of Economic Entomologists, writes us that the annual meeting of the Association for 1897, which was announced for the two days preceding the general sessions of the American Association for the Advancement of Science at Detroit, viz., August 6th and 7th, has arranged for its sessions on Thursday and Friday, August 12th and 13th, during which time Section F will hold no meetings, closing its work on Wednesday, the 11th. It is believed that this arrangement will give better satisfaction to the members of the Association of Economic Entomologists, most of whom are also members of Section F, and will be a saving of time. The Russell House will be headquarters. A new feature of interest which will be introduced this year will be reports from various foreign members of the Association on the worst insect pests of the year in their respective countries. The titles of papers should be sent promptly to the Secretary to be inserted in the provisional program. General information relating to hotel accommodations, railroad rates, etc., is given in the preliminary announcement recently issued by the American Association for the Advancement of Science, and, if any of the members have not received this circular, they may obtain it, or any other desired information of similar nature, by writing to the Local Secretary, A.A.A.S., Mr. John A. Russell, 401 Chamber of Commerce, Detroit, Mich.

Among the very numerous jubilee honors conferred by Queen Victoria we notice that Sir William MacCormac, President of the Royal College of Surgeons; Dr. Samuel Wilks, President of the Royal College of Physicians, and Mr. James Pender, who carries on much of his father's work in connection with telegraphs, have been made baronets. Professor William Crookes, Dr. W. G. Gowers and Dr. Felix Semon have been made knights. The K. C. B. has been conferred upon Professor J. Norman Lockyer, Dr. William Huggins, Mr. J. Wolfe Barry and Dr. Edward Frankland, and the C. B. on Mr. W. H. M. Christie, Astronomer Royal.

Yale University has conferred the degree of LL.D. on Dr. T. Mitchell Prudden, professor of pathology in Columbia University.

Harvard University has conferred the degree of A.M. on Professor Franklin W. Hooper, of the Brooklyn Institute of Arts and Sciences.

Trinity University, of Toronto, will confer, at the approaching meeting of the British Association, the honorary degree of D.C.L. on Sir John Evans, President; Lord Lister, Lord Rayleigh, Sir John Lubbock and Dr. Forsyth.

Mr. Ernest B. Forbes, of the University of Illinois, has been appointed Assistant State Entomologist in Minnesota.

F. V. Coville, Chief Botanist of the Department of Agriculture and Curator of the National Herbarium, has just gone to Oregon, to investigate the effect of sheep herding on the vegetation of the Cascade Range, and to conduct botanical investigations.

A DISPATCH to the London *Times* states that Lieutenant Eldred Pottinger and Mr. Lawrence, who, with a small party of Gurkhas, have been engaged for some months past in exploring the sources of the Irawadi, were attacked by Black Mairus on the night of May 22d. A native surveyor and one Gurkha were killed, and two Gurkhas were wounded. Lieutenant Pottinger and Mr. Lawrence escaped with the rest of the party, bringing the wounded men with them, and after great hardships arrived in Chinese territory.

THE death is announced of Dr. Japetus Steenstrup, formerly professor of zoology at the University of Copenhagen, and known for his contributions to natural history and paleontology, at the age of eight-four.

THE trustees of the National Portrait Gallery, London, have purchased a portrait of Sir Joseph Richardson, sometime British Secretary of State and the second President of the Royal Society. The Gallery has received by presentation a portrait of Francis Ronalds, one of the inventors of the electric telegraph, and a bust of Richard Jeffries, naturalist and author.

A BRONZE statue of Benjamin Franklin, representing Franklin seated in heroic proportions, will be presented to the City of Philadelphia by Mr. Justice C. Strawbridge and erected on the spot where Franklin laid the cornerstone of the first building of the University of Pennsylvania.

THE committee on an international memorial to the late Sir John Pender, whose appointment we announced some time since, has already received subscriptions amounting to about £6,000. It is proposed to place a bust of Sir John Pender in some suitable institution, to endow with £5,000 a Pender chair of electrical engineering in University College, London, and to establish a Pender scholarship and a gold medal at Glasgow University.

MR. JOHN RUSSELL YOUNG, a newspaper correspondent, not known to have made any study of library management or methods, has been appointed by President McKinley head of the new Congressional Library. Mr. A. R. Spofford will remain connected with the library as First Assistant Librarian. Mr. Bernard R. Green, who, with the late General Thomas L. Casey, supervised the construction of the library building, has been appointed Superintendent of the Buildings and Grounds.

SECRETARY SHERMAN has, under an authorization in the recent sundry civil appropriation bill, changed the title of the Bureau of Statistics of the State Department to that of Bureau of Foreign Commerce. The old title tended to confusion with other bureaus and did not properly describe the work of the bureau, which deals with the collection of reports of consular officers on foreign commerce and their distribution to the business community.

A COMMITTEE has been appointed by the Treasury Department to make an investigation of the U. S. Coast and Geodetic Survey, with a view to learning whether the efficiency of the department, especially its field work, can be improved. Professor W. G. Reymond, of the Rensselaer Polytechnic Institute, and Mr. Octave Chanute, of Chicago, have been appointed members of the committee, one place remaining to be filled.

THE New York Zoological Society has begun the publication of a *News Bulletin*, intended to increase interest in the work of the Society. The first number contains, in addition to items of news, an illustrated articles on the Zoological Park, reprinted from *Harper's Weekly*. The Society proposes to hold, next winter, an exhibition of paintings and sculptures of American wild animals. The plan for the grounds and buildings of the park will soon be completed.

THE specifications for the new wing of the American Museum of Natural History, New York, have been approved by the Park Board, and bids for the building will soon be opened.

THE Natural History Building of the University of Illinois was struck by lightning on the morning of June 17th, and partially destroyed. The collections, apparatus and libraries of the Illinois State Laboratory of Natural History, the Biological Station and the Agricultural Experiment Station were saved, with slight damages by water. The damage to the building is estimated at $3,000. The loss in apparatus, principally in geological and botanical departments, is nearly $5,000.

THE steamship Hope, commanded by Captain John Bartlett, has been again chartered by Lieutenant Peary, who will leave Boston to join the steamship between July 10th and 12th.

THE daily papers state that additional details of the eruption of the Mayou volcano, in the Province of Albany, Philippine Islands, show that 120 of the inhabitants of the village of Liboug perished. The village was greatly damaged and the tobacco crop of the vicinity was destroyed. The eruption was accompanied by an earthquake, the shocks being felt over an area of one mile. The volcano of Mayou has not been active since 1617.

THE third session of the Greenacre lectures opened on July 1st and will continue until September 3d. Daily lectures are given on subjects of scientific, literary and philosophical interest. The congress will take advantage of the meeting of electrical engineers at Greenacre and announces as part of the program lectures by Professors Barker, Brackett, Duncan, Crocker, Pupin, Cross and others.

THE International Institute of Bibliography at Brussels announces the holding of its second conference, August 2–4, 1897.

THE *American Journal of Archæology*, hitherto edited by Professor A. L. Frothingham, Jr., has been transferred to the Archæological Institute of America, and will hereafter be published in a second series by the Macmillan Company. Professor John H. White, of Harvard University, will be the editor-in-chief, with Professor James R. Wheeler, of Columbia University, and Professor Allan Marquand, of Princeton University, as assistant editors.

DR. PERSIFOR FRAZER, who, at the wish of the late Professor Cope, has been for two months acting as managing editor *pro tem.* of the *American Naturalist*, has been succeeded temporarily by Mr. A. M. Brown, of Philadelphia.

Natural Science calls attention to the fact that over a century ago there was founded a zoological record, viz., F. A. A. Meyer's *Zoologische Annalen*, which was published at Weimar in 1794, and ran for one year only. Meyer gave an account of zoological works issued up to Easter and up to Michaelmas, 1793, an aphabetical list of all living zoologists, an account of all the zoological collections known to him, and a sketch of all the new animals described during the year, in systematic order.

MR. A. W. BENNETT will succeed Professor F. J. Bell as editor of the Journal of the Royal Microscopical Society.

A *Zeitschrift für comprimirte und flüssige Gase*, edited by Dr. M. Altschul, will herefter be published in Berlin by L. Esterman. The first number was opened by an article by Professor Raoul Pictet, followed by articles by Professor H. F. Wiebe and Professor M. Thiesen.

IT is noted in *Industries and Iron* that according to a recent American Consular report, at a place called Tongshan, about eighty miles from Tien-tsin, the Chinese have established extensive railway carriage building works, in which the rolling-stock for the extension of the railway is being constructed. Only the axles, wheels, springs and couplers are imported, and the Consul expresses himself as surprised at the excellence and finish of the passenger carriages turned out by native labor. The Chinese Engineering and Mining Company have attained an output of 2,000 tons of coal daily from the mines in the vicinity, and large extensions are being contemplated.

WE have already announced that next year Captain Sverdrup proposes to take the Fram up Smith Sound to the northwest coast of Greenland, for the purpose of prosecuting explorations in that direction. The London *Times* states that, though Dr. Nansen will not accompany the party, there is reason to believe that he is taking an active share in the direction of the expedition. The object will be to penetrate north through Smith Sound and Robeson Channel as far as possible along the northwest coast of Greenland. An attempt will be made to discover how far Greenland extends northward, and to survey the northwest, north and northeast coasts. In short, one prime object will be to complete the exploration of the Greenland coast, a considerable extent of which is still quite unknown. It will be remembered that Lieutenant Peary carried explorations further eastward than had been previously

done. The task will be a difficult one, even if Captain Sverdrup succeeds in taking the Fram through the difficult ice navigation which is generally found between the Greenland and American shores. Still, as we know from Hall's experience, there are years when the passage is quite clear, and if the conditions are favorable the Fram may succeed in reaching 82° N. without difficulty. Dr. Nansen is also anxious that Captain Sverdrup should examine what has been called the 'paleo-crystic ice,' about which there has been so much discussion, and as to the origin and real character of which there is considerable doubt. An attempt will be made to discover how far one must travel from land with dogs and sledges before meeting with ice more like that in which the Fram drifted.

COMMISSIONER HERRMANN, of the General Land Office, has formulated, for the approval of the Secretary of the Interior, Regulations for the Forestry Reserves of the United States, following the recommendations of the Committee of the National Academy, published in a recent issue of this JOURNAL. Attention is called to the danger of forest fires and to the law providing for punishment by fine or imprisonment, not only for willfully setting fire to any timber on the public domain, but also for letting fires burn unattended near any timber. The recommendations would allow prospecting and the development of mineral resources, and land for school houses and churches are provided. The construction of wagon roads and irrigating canals is permitted. The pasturing of live stock is allowed, except of sheep in regions where the rain fall is limited. Owners of mines and settlers resident within the forest reserves are permitted to take firewood, fencing and building material when they have not a sufficient supply on their own claims. Provision is also made for the sale of timber when this will not interfere with the value of the forests. Instructions are issued to all special agents of the Interior Department regarding the prevention of injury and depredations. It is further provided that lands more useful for mining or agricultural purposes may be eliminated from the forest reserves and restored to the public domain. Subject to the surveys now being made by the Geological Survey, portions of the suspended reserves may be restored to public entry, and other portions of the public domain may be included in them.

AN article in the London *Times* entitled 'On the Trail of a Ghost,' regarding an alleged haunted house in Perthshire, Scotland, has been followed by numerous letters on the subject. Two of these, one by Professor John Milne, offer the plausible explanation that the noises are of seismic origin. Perthshire is a center for British earthquakes. As early as 1840 the British Association appointed a committee to investigate the Perthshire earthquakes, and instruments were established in the parish church at Comrie. As many as 465 shocks were noted there between 1852 and 1890, and sounds may be heard when no movement can be either felt or recorded by an ordinary seismograph. Mr. Milne suggests that "The Society for Psychical Research when on bogey-hunting expeditions might possibly find that the suggested use of tromometric apparatus might not only lay home-made ghosts, but would furnish materials of value to all who are interested in seismic research."

WE learn from *Industries and Iron* that the Lachine Rapids, Hydraulic and Land Company, organized in 1895, to use the great energy of the Lachine Rapids, near Montreal, will soon complete its installation. There will be about eighty-six turbine wheels shortly in operation, and twelve dynamos making 175 revolutions each with a generating pressure of 4,400 volts. The electric energy will be carried by overhead wires as far as the outskirts of Montreal, and then passed underground until it reaches the substation in the city.

THE supply bill passed at the recent session of the New York Legislature contained an item appropriating $10,000 for the medical department of the University of Buffalo to investigate the causes, nature and treatment of cancer. Governor Black vetoed this appropriation with the statement: "I cannot approve a proposed policy which requires the State to engage in an investigation of the causes of various diseases with which the human family is afflicted. I think that the interest of the people themselves

and the skill, intelligence and enterprise of physicians may be depended upon to make an investigation."

THE laboratory courses in biology at Wesleyan University will be conducted next year by Mr. Estin during the absence of Professor Conn in Europe.

THE Berlin correspondent of the London *Times* writes that, at the recent Medical Congress, Professor Liebreich, who may, perhaps, be described as the leader of the anti-Koch party in the Berlin scientific world, stated his theory of tuberculosis as opposed to Professor Koch's. Phthisis, he said, might be present without tuberculous bacilli as concomitants. The reception of tuberculous bacilli into the system had an injurious effect only in cases where there existed a predisposition to disease, and thus the bacilli were only parasites. It was a radically false method to attempt merely to deliver a consumptive patient from the presence of bacilli. The chief thing was to increase the vital power of the cellular tissue. Cantharidine was a specific capable of producing this result. Was there any method of disinfecting the cellular system? In Professor Liebreich's experience he found that etherized oil of mustard had this effect. The lecturer did not think that the therapeutic systems which had been built up on the basis of bacteriology were defensible. The results obtained with diptheritic serum were apparent rather than real. Professor Koch's method of treating tuberculosis had no prospect of ultimate success. Professor Liebreich's views were summarized in the sentence: "Tuberculosis is a 'nosoparasitism,' and the essential feature of the disease is the deterioration of the organism." Several subsequent speakers of eminence strongly combated Professor Liebreich's assertions, urging in particular the indubitable successes obtained with diphtheritic serum.

UNIVERSITY AND EDUCATIONAL NEWS.

THE Hull Biological Laboratories of the University of Chicago were formally dedicated on July 2d. The presentation was made by Miss Helen Culver and the acceptance acknowledged by the President. The dedicatory address was made by Professor William H. Welch, of the Johns Hopkins University, his subject being 'Biology and Medicine.' The laboratories were open to inspection in the afternoon. A dinner was given to the visiting biologists before Professor Welch's address and a reception was given afterwards by the members of the biological faculties to Miss Culver and Professor Welch.

THE University of Chicago will erect a new building outside the University grounds which will contain the plant for power, light and heat, the extensive printing and bookbinding establishment and a retail bookselling and stationery department.

THE trustees of the College of the City of New York have approved the purchase of a site on Convent Avenue, and have authorized the executive committee to select plans for the buildings.

PRESIDENT G. J. KOLLEN, of Hope College, situated at Holland, Mich., announced at the recent commencement that $100,000 had been subscribed for the College by various donors.

BY the will of the late Dr. John T. Atwater, of Poughkeepsie, N. Y., Yale University receives land valued at $25,000.

THE Ohio Supreme Court has handed down a decision that gives the Ohio State University the estate left by the late Mr. Henry F. Page, consisting of farms and personal property, the exact value of which is not known.

THE Thirty-fifth University Convocation of the State of New York met at Albany from the 28th to 30th of June, with a large attendance of those interested in higher education. Addresses were made by Chancellor Upson, Governor Black and President Canfield, of the Ohio State University. The first morning was devoted to the teaching of science, papers being presented on the 'Present Trend of Geography,' by Professor W. M. Davis, Harvard University; on 'Methods of Teaching Botany in the Secondary Schools,' by Professor Geo. F. Atkinson, Cornell University; on 'The Proper Use of Library and Laboratory in Teaching Physical Science in

the Secondary Schools,' by Professor John F. Woodhull, Teachers' College, New York; on 'The Practical Study of the Brain in a Primary School,' by Professor Burt G. Wilder, Cornell University, and on 'The Place of Electricity in the College Curriculum,' by Brother Potamian, Manhattan College. These papers were discussed by Professor A. P. Brigham, Colgate University; Professor E. L. Nichols, Cornell University; Professor W. LeConte Stevens, Rensselaer Polytechnic Institute, and others. Among other subjects considered by the convocation were Athletic and Oratorical Contests, Instruction in Ethics in Secondary Schools, The Relations of the College to the University and a National University, under which latter subject Professor R. H. Thurston, Cornell University, read a paper entitled, 'The National University and Technical Education.' In some remarks on the work of the University, Regent T. Guilford Smith called special attention to the work in geology and botany of Dr. F. J. H. Merrill and Mr. J. A. Lintner.

THE New York State Teachers' Association met at the Normal College, New York, from June 30th to July 2d, with about 2,000 members in attendance. There was a nature study section in which papers were read on 'Nature Study in a Crowded City,' 'The Use of the Microscope,' 'The Mounting of Botanical Specimens,' 'Literary Aids,' and other subjects of interest to teachers of science in the schools. A State Society for Child Study was organized with Mr. George Griffith, of Utica, as President, and Professor M. V. O'Shea, recently elected professor of pedagogy at the University of Wisconsin, as Secretary and Treasurer.

DR. CHARLES E. BEECHER has been promoted to a University professorship of historical geology at Yale University, and Dr. L. V. Pirsson to a professorship of physical geology in the Lawrence Scientific School.

DR. F. E. HULL, of Toronto University and the University of Chicago, has been appointed to the chair of physics in Colby University, vacant by the resignation of Professor William A. Rogers.

THE following promotions and appointments have recently been made by the Trustees of the Johns Hopkins University: John M. T. Finney, M.D., now associate, to be associate professor of surgery; Lorrain S. Hulburt, Ph. D., now associate, to be collegiate professor of mathematics; James E. Humphrey, S.D., now lecturer, to be associate professor of botany; William J. A. Bliss, Ph.D., now assistant, to be associate in physics; N. Ernest Dorsey, Ph. D., now fellow, to be assistant in physics; William T. Mather, Ph.D., now fellow, to be assistant in physics; George B. Shattuck, Ph. D., now fellow, to be assistant in geology; Oliver L. Fassig, S.B., of the U. S. Weather Bureau, to be instructor in climatology; Charles R. Bardeen, M.D., to be assistant in anatomy.

FELLOWSHIPS at the Johns Hopkins University have been awarded as follows: F. S. Conant, Zoology (the Bruce fellowship); Cleveland Abbe, Jr., Geology; G. A. Drew, Biology; C. W. Greene, Biology; J. G. Hardy, Mathematics; W. A. Jones, Chemistry; C. E. Mendenhall, Physics; S. A. Mitchell, Astronomy; J. L. Nichols, Pathology; E. E. Reid, Chemistry, C. W. Waidner, Physics. It appears that these awards represent four notable instances of heredity either of 'nature' or of 'nurture.'

THE White professorship of moral philosophy at Oxford, vacant by the death of the late Professor Wallace, has been filled by the selection of Mr. John Alexander Stewart, tutor of Christchurch, and known as the editor of Aristotle's *Ethics*.

THE allowance made from the public funds for the English University Colleges and for the College at Dundee has this year been increased from £15,000 to £25,000. On the recommendation of a committee, consisting of Mr. T. H. Warren, President of Magdalen College, Oxford, and Mr. G. D. Liveing, professor of chemistry, Cambridge, the apportionment has been made as follows:

The Owens College, Manchester......	£3,500
University College, London............	3,000
University College, Liverpool.........	3,000
Mason College, Birmingham...........	2,700
King's College, London................	2,200
Yorkshire College, Leeds...............	2,200
Durham College of Science.............	2,200
University College, Nottingham......	1,500

Firth College, Sheffield..................	1,300
University College, Bristol.............	1,200
Bedford College, London..............	1,200
University College, Dundee...........	1,000

DISCUSSION AND CORRESPONDENCE.

A PLEA FOR 'SCIENT.'

TO THE EDITOR OF SCIENCE: I wish to ask you not to use 'Scientist' in the pages of SCIENCE any longer, but to employ in its place the term 'Scient,' which is already well known in English in such compounds as 'omniscient' and 'prescient.' 'Scientist' appears to have been formed from 'Science' after the fashion of Artist from Art, but the 't' is an unfortunate intruder, and the better derivative would have been 'Sciencist.' But 'Scient' is shorter and much more correct. Moreover, it is the exact equivalent of the French term 'Savant,' which is frequently used in English also, but generally in a more or less derisive sense. Therefore, let us in future say 'Scient' (= 'sciens,' a man that knows) to which there is no possible objection, and which is already in frequent use in composition.

T. L. SCLATER.

ZOOLOGICAL SOCIETY OF LONDON,
June 23.

[It is easier to name a hundred species than to give currency to one obsolete word. The word 'Scientist' was introduced by the late Dr. B. A. Gould. It is not used in editorial contributions to this JOURNAL, but being a useful word, correctly formed (from *scientia; cf.*, scientific), it bids fair to outlive its ugly associations, perhaps more quickly in Great Britain than in the United States.—ED. SCIENCE.]

SHARPENING MICROTOME KNIVES.

SINCE Professor Minot has brought into prominent notice* Moll's method of sharpening microtome knives, it might be of interest to call attention to the fact that in an earlier paper† Moll describes a very useful part of the method which is not mentioned in the article cited by Professor Minot. It consists simply in the use of emery and water on plate glass to grind the knife into shape and to renew the edge when it has been injured in any way. After trying numerous abrasives, including the particular grades of emery used by Moll, I discovered that carborundum is by far the best for this purpose. It is so extremely hard and is supplied in such uniform grades* that it is possible after the knife has once been ground to shape to grind out a bad nick in a few minutes, which greatly minimizes the annoyances of cutting resistant tissues. After the edge has been smoothed as much as possible with the finest grade of carborundum, diamantine † is used as Professor Minot describes. Moll recommends using one side of the plate for grinding and the other for polishing the edge. To grind into shape the edge of a knife or razor as furnished by the manufacturer is a matter of considerable difficulty, and here in particular carborundum or emery is almost indispensable. Those possessing microtomes in which razors can be clamped will probably find it more convenient to obtain thick razors already ground to shape and with the superfluous part of the cutting edge removed, as advocated by Moll. Such razors, of good English manufacture, slightly hollow-ground, and having a cutting edge measuring about 14–16°, are sold by P. J. Kipp & Zonen, Delft, Holland, for $2.50. (A glass plate mounted on a wooden block for sharpening the same can be had for $1.25.) These razors are rigid, in this respect very different from the thin, very hollow-ground ones usually found on the market. They have an advantage over knives in being more easily handled, besides being cheaper and easier to protect from injury when not in use.

WALTER T. SWINGLE.

SCIENTIFIC LITERATURE.

The Ancient Volcanoes of Great Britain. By SIR ARCHIBALD GEIKIE. London, Macmillan & Co., Limited. New York, The Macmillan Company. 1897. 2 vols., Imperial 8vo, with seven maps and many illustrations.

The title of this work is hardly commensurate with the scope of its subject-matter. Since the author's characteristic modesty has restrained him from giving it a name adequately expressing its magnitude and importance, he may kindly permit his readers to name it for him in full and call it more justly: A treatise on vulcanology exemplified chiefly by the ancient volcanoes of Great Britain. Such a treatise is needed. The time is come when the cumulative gains of our knowledge of volcanoes acquired during the last twenty years should be reckoned up and an account of stock taken, when bad assets should be sponged out and doubtful ones appraised at reasonable estimates. Nearly every branch of science needs a periodic overhauling and a revised statement of its general facts and principles in the light of its most recent advances. It is long since volcanic geology has had a satisfactory one. But it has one now at the hands of a master. The method of treatment, the logical order of the constituent parts, the arrangement of its wealth of material, are such as to enable the reader to see, as clearly as the present state of the science permits, the relations of parts to the whole and of facts to principles. The broader generalizations which have thus far been reached concerning the nature of volcanic action, its products and their modes of occurrence, are first stated. They are put forward briefly and conservatively, and no words are wasted in needless discussion. This presentation of the subject of vulcanism in general is the object of the first seven chapters, or Book I. The remainder of the work is a detailed discussion of the volcanic phenomena of the British Islands. The arrangement or plan of this discussion is doubtless the best one that could be selected. It begins with the most ancient, advances through the succeeding geological ages in their regular order, and ends with the most recent. The broader and more general facts laid down in Book I. are the guiding principles of this discussion, and the vast array of concrete facts becomes the foundation upon which the principles and generalizations repose. It will be interesting to glance, necessarily in the briefest manner, at the special points of interest in this work.

The first chapter is in the nature of a prelude or exordium preparatory for what is to follow. It points out what geologists of other countries might otherwise fail to realize, that the British Islands have peculiar advantages for this study because of the remarkable completeness of the geological record, the exceptionally full development of volcanic activity in nearly all geological ages, and the advantageous manner in which its results are exposed to view by denudation. American geologists may find difficulty at first in realizing this, but the author makes it certain. And so this little island, which would be buried half a mile deep in a fraction of the lava which swamps our northwestern States, proves to be as fruitful in material for the edification of vulcanology as it has been for the advancement of civil liberty and civilization. In the work at large we find such a wide range and variety of volcanic phenomena that the rest of the world is not likely to furnish many that are much more valuable, or that would materially affect the inductions drawn from those of Britain, though other regions may furnish occurrences which seem to be absent there.

The second chapter speaks of the causes of volcanic action. It is, therefore, a very short one, for alas! how little we know of those causes. Just here we are fortunately not concerned with the discussion of them, but merely with the way in which the author treats them. He says just enough to indicate his acquiescence in the contractional hypothesis, of which the extrusion of molten magmas within the earth is regarded as a concomitant. Conjoined with this is the intense elastic or explosive force of the vapors occluded in those magmas and which we see escaping from them during the act of eruption. The causes of volcanic action constitute the darkest and most discouraging problem in physical geology, with the exception of the causes of regional elevations, which may perhaps be only another phase of the same mystery.

To a wise and prudent man no chapter could be more embarrassing and disagreeable to write than this one. In truth, the science has no newly established inductions to record which help to solve this mystery. It is just where it stood twenty years ago.

But if the second chapter is unsatisfactory by reason of the obduracy of the subject and the lack of progress to announce, the third and fourth chapters are the reverse. In these are described the materials brought by eruptions to the surface and their modes of occurrence. Along this line there has been great and rapid progress and our knowledge is fast taking shape. Since the time of Sorby the petrographer's microscope has yielded a world of knowledge of the constitution of rocks and opened the way to the solution of many questions. The field observation of erruptive material has also become more accurate and discriminating. The author's treatment of the whole subject, though brief and much condensed, is admirable. The field geologist of long experience among the volcanics will keenly realize the practical and accurate way in which every important feature is described and its significance interpreted. As we read it, it all seems simple enough. But it is that simplicity which is the result of great knowledge and experience, clarified by many years of laborious thought and frequently revised expression of it in writing. Especially gratifying is the broader or primary basis of his classification of the lavas. It is the strictly chemical one and there should be no other. In fact, most geologists have now adopted it by common consent. The classification by contained minerals and texture can only be secondary and subsidiary. In the earlier stages of microscopic petrography there was an apparent tendency on the part of many able investigators to make everything turn upon mineral contents and it proved to be a serious clog upon the results of their researches. New facts in extraordinary abundance, and many of them of high import, were brought to light, but the methods of grouping them often selected rendered them barren of generalizations. It is a matter of vast importance how we group volcanic rocks, for it profoundly influences the directions and limitations of our speculations concerning their genesis and primitive condition within the earth. The descriptions of the rock textures, their appearance to the naked eye and in the microscope, and the explanations of the terms which are commonly used to designate their many varieties, are all excellent and the examples well chosen. The descriptions of lava sheets follow. The clastic volcanic materials, conglomerates, agglomerates, tuffs and volcanic dust are given careful and accurate attention. The finer material is worthy of especial study in this country, where it has not hitherto been followed up with the diligence it deserves.

The fourth chapter is devoted to the especial consideration of materials errupted at the surface and to the types of volcanic piles, three types being taken, the Vesuvian, the Plateau or fissure and the Puy types.

The fifth chapter deals with the underground phenomena, the vents themselves and the necks or cores left in the passageways of the lavas to the surface being described with great fullness. It is a favorite theme of the author and he invests it with the liveliest interest.

The next, or sixth, chapter treats of dykes and the subterranean intrusive masses in the forms of laccolites and sheets of lava forced in between sedimentary beds. Finally he discusses those remarkable and singularly interesting intrusions named bosses, which are often so puzzling and hard to understand and which look as if a vast mass of relatively soft or plastic material had been trying to punch an immense hole or passageway upwards through hard, rocky strata and at the same time to preserve its identity and general shape with comparatively little deformation. This paradox is often seen in our Western mountains and is the problem of the so-called dome structure and eruptive granite of California and Colorado.

The remainder of the work, and much the greater part of its bulk, is a detailed description of the volcanic relics of the British Islands. It begins with the eruptions of the Archæan and ends with those of the Tertiary. The whole mass of material is arranged so as to constitute a geological history of vulcanism and also so as to show it in its relations to the geological evolution of the land. It is not light reading and is not a study for children. But to the ex-

perienced it is of profound interest from beginning to end. Each geological age is made a chapter, or series of chapters, by itself and is prefaced with a short, clear exposition of the general geology of that age as represented in the British formations, thus preparing the way to the easiest understanding of the relations of the volcanics to the geology at large. The first one will be of deep interest to all geologists, and to many it will be the most fascinating. For it treats of the pre-Cambrian rocks and the mystery of the 'fundamental complex.' In a few paragraphs he sketches in outline the state of knowledge of the rocks which underlie the oldest known sediments of Britain. Here, at the uttermost bounds of geological knowledge and in the dim light of the earliest known order of things, we find remnants of volcanic action. The admirable studies of Teall among the Lewisian or 'fundamental' gneisses of Murchison, exposed in the northwest of Scotland and in the Hebrides, leave little doubt that the great bulk of them are plutonic igneous rocks. They differ in no essential respect from those deeply buried bosses or intrusions of later ages which are known to be connected with surface eruptions and constitute the subterranean portions of the outflowing masses. But beds clearly contemporaneous and erupted at the surface have nowhere been identified, and interbedded clastic volcanic formations are also absent. On the other hand, the Archæan complex is traversed by innumerable dykes, which are certainly older than the oldest rocks which overlie the complex, and their volcanic nature is unmistakable. It is interesting to compare this with the conclusions reached by American geologists in the 'basement complex' of Canada and Lake Superior, where the facts are of the same nature and the conclusions are the same, except that surface eruptions both massive and clastic are recognized in abundance.

Sir Archibald still retains the name 'Lewisian gneiss' as originally given by Murchison. Why have our geologists been so shy of the good old name, Laurentian, given by Logan? Certainly a rose by any other name will smell as sweet, but what is the use of the other name? The extreme caution and candor of Irving (R. S.) were lovable, but they did not call for a new one. The old one would have misled nobody unless the true spirit of geology were not in him. All needful reservations geologists will make for themselves.

In the same chapter the reader is carried up into the vast pre-Cambrian formations which overlie the Lewisian, from which they are divided by the great unconformity, probably the greatest in all geological time, and to the first great series the name of Torridon sandstones is given. They abound in dykes, intrusive sheets (or 'sills') and bosses, but no surface eruptions have been proven. Higher still after another great unconformity is a vast succession of crystalline schists (provisionally named Dalradian) whose age is not yet determined, but which seem in part at least to be pre-Cambrian. They too abound in eruptives and their general character suggests our own Algonkian rocks. It is obviously impossible here to note in detail the substance of the long series of chapters which carry the reader from the Archæan to the close of the Palæozoic. Only the most general summary can be given. And yet to pass thus cursorily over the many chapters relating to the eruptive masses of the Cambrian, the Silurian, the Old Red Sandstone, and, above all, the long series of chapters devoted to the Carboniferous, with all their wealth of material wrought out in such a masterly way, seems unappreciative. We are presented with an immensely long vista of volcanic action, beginning with the earliest epoch of which we have any knowledge and extending down to the close of the Palæozoic, manifesting itself in all that succession of ages. But the more ancient they are the more profoundly have the erupted materials been changed or modified by metamorphic action and disturbed by repeated earth movements with dislocations and distortions of the strata, so that the determination of their true volcanic nature has required many years of labor by hundreds of earnest workers in the field and laboratory and with the microscope. The result of this labor now seems well assured, not only in Britian, but in all other countries where geologic research is diligently prosecuted. One grand result of it is the conclusion that volcanic action has been the same in all ages. And when our thoughts reach

back to the Archæan we find that even then the world was an old world. Nor are there any visible signs that the world was then any nearer the beginning than it is to-day. Geology has thus far found nothing to tell us about the beginning of mundane things, and our notions of a primordial state of the world must come wholly from outside the domain of geology.

With the close of the palæozoic came a long age of quiescence in volcanic action. No traces of it have been discovered in any part of the Mesozoic of Britain, and only trifling ones in the Mesozoic of all Europe. But though the fact is a wide one, it is not world-wide. The eruptive masses of our own Appalachians, New England and Nova Scotia are Jura-Trias, and the vast fields of the Deccan in India are assigned to the Cretaceous. That they should have slumbered so long in Europe is remarkable, but still more so is the fact that their fires should have been awakened again with full energy in the Cenozoic and often in the same old places.

The description of the Tertiary eruptions of Britain is the theme of the greater part of the second volume. It is of especial interest to American geologists whose labors have been most largely in the far West, where the main eruptive masses are distributed all the way from early Eocene down to a time which is surely post-Glacial. The chapters on these rocks are a veritable mine of information. Remarkable indeed are the two chapters on the Tertiary dykes not only on account of the extraordinary development of these features in the island of Great Britain, but equally so on account of the thorough manner in which they have been worked up in the field and in the laboratory. Of course, it represents the labor of many investigators for several generations, but among them we know that our author is preeminent. He draws an interesting inference from them. While accepting the physicist's view of the general solidity of the earth as a whole, he concludes that during the Tertiary volcanic period not less than 40,000 square miles of Britain were underlaid by one or more reservoirs of liquid lava. This state of affairs he puts into relation with a discussion as a pure mechanical problem by Hopkins, in 1835, where just such conditions were assumed. The inferred result was the formation of fissures similar in form and grouping to those which field observation discloses.

The chapters on basaltic plateaus constitute the most conspicuous subject connected with the Tertiary eruptions. Assuredly the grandest results of volcanic action the world over are the plateau eruptions. Great piles like Shasta and Ætna, however imposing, are after all secondary in importance. The plateau eruptions of Great Britain, their extension into the far North to the Faroe Islands, and their possible connection with those of Iceland, are a grand theme and the descriptions of them are worthy of the subject. In the author's mind these plateau eruptions often take the form of the so-called fissure type as distinguished from the centralized vent, and the dykes as described in preceding chapters are regarded as the relics of fissures supplying the lavas of plateaus which have been swept away by secular erosion. In view of the great importance attached to the massive eruptions from fissures he introduces an interesting sketch of the lava fields of Iceland, which are believed to furnish the most impressive examples of recent occurrence.

American geologists will take a lively interest in the chapters which follow, describing the intrusive Tertiary rocks, especially the olivin-gabbros and the eruptive granites. We have them in this country and they have awakened warm discussions as to their real nature. Their true eruptive character is now beyond dispute, and their occurrence in Tertiary time is an important consideration in establishing the practical identity of volcanic action in the most ancient and most recent ages. The British examples are certainly admirable ones and are described with the author's usual precision and clearness.

It seems like trifling with a serious subject to merely notice in this fragmentary way a few points in this great work, which abounds in an unspeakable wealth of instructive and interesting material, all wrought out and delineated with a master hand. The arrangement is admirable. Everything is in logical order, and whatever precedes is a preparation for that which follows. The broad plan of the work is historic progression, and as we complete the

perusal we can look back through 'the corridors of time' and admire the perspective with everything in due proportion.

I regard this monograph as the greatest work on vulcanology ever written. Scrope's work on the volcanoes of central France was indeed a great one—almost an epoch-making one in its day. Nor is its force or usefulness yet spent. For it may be still read with great profit and instruction. But it was much more limited in its categories and discoursed upon the volcanoes of a single period. The work before us deals with vulcanism in all its aspects and with volcanoes of all time, and embraces a vast accumulation of knowledge, of which the world in Scrope's time knew little or nothing.

C. E. DUTTON.

Catalogus Mammalium tam viventium quam fossilium. By DR. E. L. TROUESSART. Berlin, R. Friedländer & Sohn. January, 1897. 2d ed., fascic. I., Primates, Prosimiæ, Chiroptera, Insectivora. 8°, pp. 218.

The appearance of the first part of the new edition of Trouessart's 'Catalogue of Mammals, Living and Fossil,' will be welcomed by all students of mammals, for such compilations, in spite of their inherent imperfections, are a great practical convenience.

The present part contains 265 genera and 1,294 species, which numbers, contrasted with those of the first edition (1878–81), show a falling-off of 104 genera and an increase of 200 species. The decrease in genera seems to be due in the main to different limits assigned to the orders, chiefly from the shifting of fossil genera.

The work is apparently brought down to the end of 1896, as it includes *Nesopithecus* Forsyth Major (published in October, 1896) and recent species described by Thomas. For fossil forms Rogers's 'Verzeichniss' and Lydekker's 'Geographical History of Mammals' have been consulted. Five new generic and subgeneric names are proposed, as follows:

p. 17. *Rhinostictus*, based on Sclater's *Cercopitheci rhinosticti* 1893.

p. 19. *Erythrocebus*, based on Sclater's *C. erythronoti*.

p. 22. *Otopithecus*, based on Sclater's *C. auriculati*.

p. 68. *Prosinopa* for *Sinopa eximia*.

p. 204. *Scaptogale* for *Echinogale* Pomel 1848, preoccupied.

The usual sequence of forms is reversed, the Catalogue opening with the genus *Homo*, which, by the way, is given independent ordinal value ('Ordo I. Bimana') in accordance with the antiquated Cuvierian system. *Pithecanthropus* is recognized as a valid genus—the highest anthropoid—and is the first genus given under Primates. The Lemurs are raised to ordinal rank. The classification adopted is in the main that of Flower and Lydekker (except that it begins at the wrong end), but we regret to see that Lydekker's excellent division of the old order Edentata into *Edentata* (Armadillos, Anteaters and Sloths) and *Effodientia* (Pangolins and Aard-varks) is not followed.

The matter is so arranged that the specific names, references and synonymy form a broad column on the left-hand side of the page, while the geographic distribution occupies a narrower column on the right. Unfortunately, the type localities are not given at all. The specific names are numbered consecutively and are printed in black-face type; the subspecific names are not numbered and are in italics. 'Varieties' are preceded by '*Var.*' but the author neglects to state how he imagines a 'variety' to differ from a subspecies. Synonyms are indistinguishable from the recognized subspecies, except that they lack the letter and dash [a.—] which precede the former—a hardly sufficient distinction.

By this method of treatment the distinction between species and subspecies is greatly exaggerated—a common error among authors whose knowledge of the forms treated is derived mainly from books rather than from specimens. Whether the describer of a new form accords it specific or subspecific rank depends, according to present usage, on his belief as to the existence or non-existence of intergrades connecting it with other forms, and his views on this subject are pretty sure to vary with the material at hand and the time spent in its study, and sometimes with his mood and the particular day his manuscript goes to press. Hence it is not surprising that an author often changes his attitude with respect to the status

of a particular form, treating it as a subspecies in one paper and a full species in the next. In the case of the Texas mole described as a subspecies by Dr. J. A. Allen in 1891 and raised to specific rank by the same author in 1893, Dr. Trouessart adopts a curious course. He gives it as a full species with 189*3* as the date, and then in synonymy gives the subspecific form in which it was originally described, with 189*1* as the date, showing that he was aware of the correct date. Of course, the species should date from 1891—the year in which *the animal* was named—for the date on which an author happens to change his mind as to the *rank* of a particular form has nothing to do with the date of the name. If this case represents Dr. Trouessart's views in this matter the inference is that he, like some botanists of the old school, is a worshipper of the 'combination.' He certainly agrees with these botanists in spelling personal and some other specific names with a capital initial letter—in this respect again departing from the best usage among zoologists.

Sections of genera and forms of species of earlier authors are sometimes given formal subgeneric and subspecific names, and names so given are credited to the early author instead of to himself. Thus the section 'Cercopitheci Rhinosticti' of Sclater is made the subgenus '*Rhinostictus* Sclater,' and Dr. Harrison Allen's 'Var. (b) Northern form of Vespertilio gryphus' is made 'Var. *septentrionalis* H. Allen.'

I am indebted to Dr. T. S. Palmer for calling my attention to Dr. Trouessart's extraordinary rule for the treatment of preoccupied names. If he finds such names preoccupied among mammals he promptly renames them (as *Scaptogale* nob. for *Echinogale* Pomel), but if they are preoccupied in other branches of the animal kingdom he lets them stand. Thus the generic names *Tylostoma* (p. 155), *Schizostoma* (154), *Macrotus* (152), *Mystacina* (149), *Furia* (135), *Vesperus* (106), *Megaloglossus* (98) and many others are retained, notwithstanding the fact that all are preoccupied and replaced by other names now in more or less common use. A few of the dates given for genera are erroneous. For instance, *Leuconoe* Boie '1825' should be 1830, and *Dendrogale* Gray '1843' should be 1848. *Prototalpa* is evidently an amended form of *Protalpa* and as such should date from *Prototalpa* Roger 1887 instead of *Protalpa* Filhol 1877.

Since the appearance of the first edition of Dr. Trouessart's Catalogue (1878–85) no attempt has been made to collect in one work the names of all the mammals of the world; and since all fossil as well as living species are included, the immensity of the task is apparent. Most authors shrink from such an undertaking, not only on account of its magnitude, but also on account of the extreme difficulty, not to say impossibility, of determining the status of described forms in groups that have not been recently revised. Nevertheless the work is of such great practical utility that for years to come every student of living or fossil mammals must keep a copy at his elbow and will owe its author a debt of gratitude. Dr. Trouessart is evidently a very rapid worker; we wish him health and freedom from interruptions, so that his great undertaking may be speedily completed.

C. H. M.

SOCIETIES AND ACADEMIES.

THE 96TH REGULAR MEETING OF THE CHEMICAL SOCIETY OF WASHINGTON.

THE following program was presented:

H. N. Stokes: 'The Chloronitrides of Phosphorus.' P. Fireman: 'The Ripening of Cheese and the Rôle which Micro-organisms Play in the Process.' E. A. de Schweinitz and Marion Dorset: 'The Product of the Tuberculosis Bacillus.' H. W. Wiley and W. H. Krug: 'The Standard Methods of Starch Determination.' W. H. Krug and J. E. Blomén: 'The Commercial Preparation of Nitro-napthalene.' F. K. Cameron: 'The Replacement of Chlorine by Sulphur in Alkaline Chlorides.' Wirt Tassin: 'A New Mineral.'

Dr. Stokes showed that the only members of the phosphorus Chloronitrides series $(PNCl_2)_n$, hitherto known are $(PNCl_2)_3$ (Liebig) and $(PNCl_2)_4$ (Stokes). The series is now extended to include $(PNCl_2)_5$, $(PNCl_2)_6$ and $(PNCl_2)_7$, as well as a mixture of higher polymers, not yet isolated, and terminating with a rubber-like polymer of high molecular weight. The substances are prepared by heating equimolecular weights of phosphorus pentachloried

and ammonium chloride in sealed tubes, whereby a mixture of chlorides in nearly theoretical amount is obtained. This is distilled from the open tube and afterwards submitted to careful fractional distillation *in vacuo*. The unique feature of the series is found in the fact that any member can be converted into the rubber-like polymer by heating, and that the latter, on distilling at a higher temperature, breaks down quantitatively into a mixture of all the lower members; it is, therefore, possible ultimately to convert any member completely into any other by heating and distilling alone. The lower members, up to and including $(PNCl_2)_6$ are well characterized, finely crystallized bodies, while $(PNCl_2)_7$ is liquid. Their stability diminishes with increasing molecular weight, $(PNCl_2)_3$ being unattached by boiling alkalies, while the rubber-like polymer is destroyed by boiling water. The formation of $PNCl_2$ and $(PNCl_2)_2$ could not be detected. The chloronitrides constitute the first extended series of inorganic polymers interconvertible by simple and direct means.

Dr. Fireman gave an extended résumé of the work of Duclaux and others showing that the lactic acid producing bacteria are not so important in the production of butter flavors as are the peptonizing bacteria.

Drs. de Schweinitz and Dorset stated that in studying the products of the growth of the tuberculosis bacilli in artificial media, it was noted that the reaction of the cultures usually becomes acid, and as Prudden and Hodenpyl had succeeded in producing tuberculous nodules without necrosis by the intravenous injection of dead bacilli, it seemed as though it should be possible to isolate from cultures of tuberculosis bacilli an acid substance, which is responsible for the necrosis of tissue that always takes place in this disease. After many fruitless attempts they succeeded in isolating from artificial cultures a crystalline acid substance having a melting point of 161° to 164° C. which was soluble in ether, alcohol and water, and crystallized in needle-like prisms. The solution of this substance was optically inactive and did not give the biuret action. The preliminary analysis of this substance gave a formula, like that of teraconic acid and the other properties correspond closely with this acid. Its identity if such has not yet been proved. When injected subcutaneously into guinea pigs it causes a slight inflammation and localized necrosis, and injected directly into the liver tissue by means of a hypodermic syringe it produces characteristic necrosis. The substance causes a reduction of temperature in tuberculous animals, and it seems probable that we have here the material which is responsible for the necrosis in tubercular infection.

Dr. Wiley and Mr. Krug showed that various methods depending on the polarization of the starch or its inversion products, as well as others based on direct weighing of the starch, were too inaccurate to commend themselves to the analyst. The only accurate methods depend on the eventual inversion of the starch into dextrose, which is then estimated by Allihn's method. Experiments in the preparation of the Nitro-naphthalenes showed that they can not be prepared from a-naphthalene sulphonic acid, but that the best yield is obtained with mixtures of nitric and sulphuric acids. The best results were obtained with 30° B. nitric acid, using about three times as much acid as naphthalene. The amount of sulphuric acid, used varies with the nitration degree desired, varying from 4 : 1 (nitric : sulphuric) for low melting products to 3:2 for the higher derivations.

Dr. Cameron cited some of his own experiments to show that, although it is possible in the case of some heavy metals to replace chlorine by sulphur by merely boiling the latter with a solution of the chloride, it is impossible to obtain such a reaction with alkaline, or alkaline earth chlorides even upon heating in sealed tubes at a high temperature.

Mr. Tassin gave a short description of a new mineral, but reserves the details for special publication.

V. K. CHESNUT.
Secretary.

TORREY BOTANICAL CLUB, MAY 26, 1897.

THE President, Hon. Addison Brown, presided. The evening was devoted to a lecture by Mrs. Elizabeth G. Britton, entitled 'The

Moss Flora of the Adirondack Mountains,' illustrated by lantern-slides prepared by Mr. C. H. Van Brunt, and also by numerous mounted specimens. These specimens, comprising about 150 sheets, handsomely displayed about the walls of the lecture-room, represented collections made by Mrs. Britton in the vicinity of Adirondack Lodge and Lake Placid in the years 1892, 1894 and 1896. The various locations where these mosses grew were described, including the story of a climb up Mount Whiteface. Graphic bits of description of these mosses brought out salient points as the slides indicating their structure were exhibited, and these were accompanied by numerous slides illustrating the scenery of their habitat. Among about 30 rare species enumerated were *Raphidostegium Jamesii*, not previously reported for New York State, and *Bryum concinnatum*, found only once before in the United States. Duplicates of Mrs. Britton's collection have been deposited at the State Herbarium at Albany, the main collection having been presented to the Herbarium of Columbia University. Partial sets were sent to the Brooklyn Institute, to Cornell University and to various other collections.

The subject of the lecture was further discussed by Mr. A. P. Grout and by Mrs. Britton, after whieh the Club adjourned to the second Tuesday in October, field meetings continuing meantime on Saturdays.

EDWARD S. BURGESS,
Secretary.

SCIENCE CLUB OF THE UNIVERSITY OF WISCONSIN.

MR. EDWARD KREMER discussed 'The Periodic System.' The speaker introduced his subject by giving a brief account of the earlier attempts to refer back to a prime matter the manifold forms in which material nature reveals herself to man. This line of thought was briefly traced from the early Greek philosophers to Prout. The reaction that followed Prout's hypothesis was duly emphasized. The lack of interest in Doehereiner's trials, and the modifications of these trials by others, in Newland's octaves, in Lothar Meyer's first chart it was thus explained in large part. Attention was also called to the fact that the principal interests seemed to center about the numerical relation existing between the atomic weights of the elements and that the time value of the system was not duly appreciated until this was made secondary to the natural classification of the elements according to their physical and chemical properties. Incidentally the prediction by Mardelejiff of the existence of certain elements and their discovery by others were alluded to, because with the discovery of their elements the natural law gained more general favor. What the periodic law really is was strongly emphasized, also the fact that the present arrangement of the elements according to this law is imperfect, but more recent systems were not discussed, partly for want of time. Finally the great advantage to be gained by using the periodic law as the basis for teaching advanced chemistry was demonstrated

C. S. SLICHTER reviewed Larmor's 'Theory of the Ether.' He first gave an explanation of the vortex theory of matter, including the properties of vortex rings and their mode of linking, and kinds of vibration. Hill's spherical vortex was explained by a diagram, and the possibility of building up a rotationally elastic ether from such cells was explained. Photographs of sandstone showing turbulent motion were presented for the purpose of showing the character of their structure. The intrinsic energy of the ether, radiation, action at a distance, density and inertia of common matter were then discussed, closing with a new theory of gravitation. Mr. Quantz gave the results of work on the psychology of rapid reading. They were the results of a statistical study of the mental habits and characteristics of fifty university students, showing that rapidity of reading depends chiefly upon the following factors, given in the order of their importance: (*a*) quickness of visual perception; (*b*) practice, as measured by extent of reading from childhood up; (*c*) power of mental concentration; (*d*) absence of motor-mindedness (lip movement in silent reading); (*e*) rapidity of mental operations in general; (*f*) strongly developed eye-mindedness; (*g*) scholarly ability, as determined by class study.

WM. S. MARSHALL,
Secretary.

THE ACADEMY OF SCIENCE OF ST. LOUIS.

AT the meeting of the Academy of Science of St. Louis on the 7th of June, 1897, twenty-one persons present, Mr. Robert Combs, of Ames, Iowa, presented a paper entitled 'Plants Collected in the District of Cienfuegos, Province of Santa Clara, Cuba, in 1895-1896.' The paper embraces the results of a collection extending from the commencement of the rainy season of one year until the close of the dry season the following spring, the territory covered by the collection lying between the entrance of the Bay of Cienfuegos, on the south coast of Cuba, up the bay and the river Damuji to Rodas, and extending back from the river to Yaguaramos and almost to the Cienega de Zapato, a region including nearly all kinds of soil and conditions found upon the island, except those of the mountain regions and the mud swamps. A brief statement was made concerning the origin of the Cuban flora and its affinities with that of continental Central America, rather than the geographically nearer Floridan region.

The paper comprised a full catalogue of the collections made, which had been determined at the herbarium of Harvard University, and of which several sets had been distributed to the larger herbaria.

Professor F. E. Nipher made some remarks on the difficulties yet involved in the theories of the ether.

WILLIAM TRELEASE.

THE TEXAS ACADEMY OF SCIENCE.

AT the annual meeting of the Texas Academy of Science, held in the chemical lecture room of the University of Texas, June 15th, the following papers were presented:

'The Personality of a Great Genius—Sylvester,' by Dr. George Bruce Halstead, in which the author took occasion to point out the exalted position of the higher pure mathematics and to give his estimate of Sylvester—his old friend and teacher—as a mathematician.

'Epsom Salts, Magnesium Sulphate, from Brown county, Texas,' by Dr. H. W. Harper. The occurrence of Epsomite in large quantities in Brown county, and of a purity sufficient to make it the source of an exceedingly cheap commercial product, was here announced for the first time. Dr. Harper's analyses gave the following results:

Water	40.07	40.00
Silica	21.075	21.43
Alumina and Iron Oxides	2.20	2.21
Magnesium Oxide	12.381	12.38
Calcium Oxide	trace.	
Sulphur Trioxide	24.014	24.01
	99.74	100.03

Calculated to contain 76.13 % $MgSO_4.7\ H_2O$.

A series of experiments demonstrated that the crude material yields crystallized $MgSO_4$ within one or two % of the analyticai results.

'Some Texas Oil Horizons,' by Hon. E. T. Dumble. The Oil Horizons in Texas range from the Carboniferous to recent formations. I. The lowest horizon in the State is in the Bend division of the Carboniferous—the black shales of the Colorado river near Brownwood. They are apparently a continuation of the asphalt deposits of Indian Territory, as indicated by the finding of similar fossils. II. The lower beds of the Cretaceous—the Trinity Sands—in Jack, Montague and Burnett counties. III. The Eagle Ford Shale (Benton) of the Cretaceous, as, for example, in the well at Fiskeville, which furnished a little oil, and in the railroad cut south of Austin, where, it is said, the shale will burn. IV. The Black Marls of the Black Waxy Prairie Division of the Cretaceous. The well at Corsicana encounters at 1,040 feet a 15-foot oil sand. Oil will also be found eastward to Smith and Anderson counties. V. The Nacogdoches horizon, which seems to be the eastern appearance of the oil and asphalt deposits of California.

'Pedagogical Note on Mensuration,' by Professor Arthur Lefevre.

'The Texas Permian,' by W. F. Cummins (read by title).

'On the Bio-Geography of Mexico and the Southwestern United States,' by C. H. Tyler Townsend (read by title).

The following officers were elected for the ensuing year: President, Dr. George Bruce Halsted: Vice-President, Professor T. U. Taylor; Treasurer, Hon. E. T. Dumble; Secretary, Professor W. W. Norman.

FREDERIC W. SIMONDS.

*ON THE THEORY OF ORGANIC VARIATION.**

As the evolution question becomes more and more deeply examined the particular phenomena described under the terms variation and heredity are concentrating much closer observation and thought. The whole philosophy of the matter seems to turn upon the interpretation of these phenomena.

* An address delivered before the Philosophical Club of Yale College, April 1, 1897.

In this discussion biologists and those who are engaged in adjusting biological theories to the systems of human thought appear to be resting on the assumption that the great result of the speculations of the last fifty years has been the furnishing of a rational explanation of the so-called natural causes of variation of organisms in their morphological and physiological aspects. This assumption appears to be associated with another, which in some sense is its antithesis, *i. e.*, that those organic phenomena which recur in relatively uniform cycles in successive generations of organisms are fundamental, are the expressions of the intrinsic nature of organic matter, and thus lie beyond the immediate investigation of science. According to this view, heredity (*a*) is not caused, but is a primary law of all organisms; variation (*b*) is a departure from the strict operation of the law of recurrence in generation; and thus external environment (*c*), or the general conditions of being in which organisms exist, is effective in its interaction with the intrinsic energies of the organism in diverting or modifying the natural expression of those energies, to the causing of that diversity and heterogeneity of form and operation which we see about us. This is, as I understand it, a fair expression of the general attitude of thinking men toward the problem in question. This position has received little consideration because it has

been taken for granted as a fundamental truth. It may be tersely expressed in the following form:

1. Heredity is a fundamental law of all organisms.

2. Variation is an acquired law of organism, and is determined by the interaction of the heterogenous environment upon the otherwise uniformly operating organic matter.

It is the validity of these two propositions that I would call in question and discuss. Is heredity acquired? When the attempt is made to state with precision what takes place in the phenomena of organic evolution the question arises: What is the relation which variation bears to heredity as a factor in the case? Which is fundamental; which is acquired?

In order to make the real point of the case clear, let us take an analogy from the field of physics. In astronomical phenomena the planetary bodies are observed to be in rotary motion about the sun and about their own axes; is the rotary motion fundamental or acquired? The first law of Newton is this: "Every body continues in its state of rest, or of uniform motion in a straight line, except in so far as it is compelled by force to change that state." And force is defined as "whatever changes the state of rest or uniform motion of a body." According to these accepted laws of mechanics, rotary motion must be regarded as secondary to direct motion or translation. In order to explain rotary motion, the law of gravity is brought in, and the circular motion is defined as the resultant of the motion of translation adjusted to the gravitation of the masses of matter in motion.

From this analogy the real nature of the problem may be inferred when we ask what is the relation which heredity bears to variation in the field of biology? If it be a fundamental law of organisms to repeat themselves in cycles of generation, to adopt the analogy of mechanics and physics, it is essential to postulate some force to account for any deviation from such hereditary cycles. If, on the other hand, variation be the primary law of organism, the postulated force is required to account for the repetition: such a force would operate first in checking the variation. It will thus be seen that the explanation of the phenomena of life will be greatly modified according as one or other of these hypotheses be assumed to be true.

If we look back over the history of opinions in natural history we discover that a century ago the whole philosophy of organisms was dominated by the Cuvierian notion that species are immutable; *i. e.*, that the cycles of phenomena presented in the development of an individual organism in the passage from the embryo to the adult stages are the same for all members of a species; that this uniformity in expression of development by the individual is the mark or distinguishing characteristic of each species, and therefore that variations, or departures from this fixed law, are accidents due to the disturbing effects of outward environment upon the individual, and cannot be transmitted to offspring by the ordinary laws of heredity. It was this conception of the immutability of species which made 'special creation' of species seem to be a rational theory, and it was the calling in question of the immutability of species which was supposed to limit the capacity of creative force in the universe.

Lamarck advanced the theory that species are not fixed, but are mutable; and he was supposed to be attacking the very foundations of natural history; he was laughed at and his theory was, for the time, silenced by the weight of authority and the common opinion of naturalists. One of the strongest arguments used against his theory was the very fact of species as

they were then known to science. If they are mutable, it was argued, how would it be possible to separate so many which are known as perfectly distinct and not even capable of crossing so as to mix one with another. Sterility was seen to be an impassable barrier distinguishing one species from another, and, as the individuals of one generation are to be accounted for only as descendants of a previous one, how would it be possible to make this barrier on the theory that the law of each species is not fixed and immutable? But although the theory of mutability of species was thought to be absurd a century ago, and was supposed to contradict the fundamental principles of natural history, the idea of specific mutability has now become an established truth in our philosophy of organisms, and variability, or the power of the organism to *divert* from the current paths of development of its ancestors, has become the important factor in evolution. We find, in fact, Bateson, in his elaborate treatise on variation,* saying: "Variation whatever may be its cause, and however it may be limited, is the essential phenomenon of evolution; variation, in fact, is evolution" (p. 6).

When we follow up the history a step further we discover that the theory of mutability of species is built directly upon the Cuvierian philosophy, but it is by breaking down the distinction between varieties and species as originally understood. Lamarck and Darwin both accepted the old conception of the normal or fundamental uniformity of the processes of generation, but, recognizing the fact of departure from this uniformity, assumed that the variation is due to the active adjustment by the organism of its structure to changed conditions of environment (Lamarck); or, the variations being spontaneous or accidental, they are preserved and transmitted in generation from parent to off-spring (Darwin).

Both schools and, so far as I have observed, the great majority of all those who discuss these problems, have started with the assumption that the normal province of what is called by the general name of reproduction is the cyclical repetition of phenomena expressed in the ancestors, *i. e.*, that the phenomena will be alike unless some cause can be discovered for their dissimilarity. Hence to discover the cause of differences has been the chief purpose of observers and speculators.

Darwin's ideas regarding the nature of variability in organism are clearly set forth in his 'Origin of Species.' In the first chapter on 'Variation under Domestication,' under the general title 'Causes of Variability,' we find this significant sentence: "It seems pretty clear that organic beings must be exposed during several generations to the new conditions of life to cause any appreciable amount of variation, and that when the organization has once begun to vary it generally continues to vary for generations" (p. 14). A few sentences further on are these words: "It has been disputed at what period of life the causes of variability act," and "I am strongly inclined to suspect that the most frequent cause of variability may be attributed to the male and female reproductive elements having been affected prior to the act of conception," and again: "When any deviation of structure often appears, and we see it in the father and child, we cannot tell whether it may not be due to the same cause having acted on both" (p. 19). Again in the chapter on 'Laws of Variation:' "Nevertheless, we can, here and there, dimly catch a faint ray of light, and we may feel sure that there must be some cause for each deviation of structure, however slight"

*Materials for the study of variation treated with special regard to discontinuity in the origin of species, by Wm. Bateson. 1894.

(p. 121). And the closing sentence of this chapter: "Whatever the cause may be of each slight difference in the offspring from their parents, and a cause for each must exist, it is the steady accumulation, through natural selection, of such differences, when beneficial to the individual, that gives rise to all the more important modifications of structure by which the innumerable beings on the face of this earth are enabled to struggle with each other, and the best adapted to survive" (p. 153).

I quote thus freely from this standard author and classic treatise on evolution, in order that we may see what the assumption in the case actually is, and also to show that it is a fundamental assumption at the very foundation of the current philosophy of evolution. The quotations are sufficient to show that it was assumed that particular variations are particularly caused, *i. e.*, while variability may be regarded as the possibility of varying, or the latent capability to vary, each variety was, by Darwin, considered to be caused by a special something with which the organism comes into relation and which did not operate upon its ancestors.

I do not propose here to discuss the metaphysical question as to whether an organism may or may not be said to possess powers or potencies, properties or capabilities, or whether it is necessary or not to assume that an organism is capable of varying before it does vary. But in this paper attention is called to the relation which a certain class of biological phenomena bear to another class of biological phenomena, and, so far as it may be possible to confine one's attention to them, these phenomena alone will be considered. From this point of view variation is a deviation, in the order of sequence, of one series of phenomena from some other order of sequence with which it is compared. In the case of organisms the latter series of phenomena is that which the parent form (A) exhibits in the course of its growth from the ovum to maturity. The case we compare with it is the series of phenomena expressed by an offspring (B) in passing from the ovum to the mature stage. A variation occurs whenever, in any particular stage of the series, B varies or deviates from the series A. Supposing such a deviation to take place the morphological character (v) expressed in the structure of the organism (B) is often and may properly be called a variation. The whole organism B, with its added character (v), is often spoken of in biology as a variety of A, and all descendants of A exhibiting the variation (v) are said to be of this variety (Bv). As I understand the Darwinian doctrine (and I believe this is the generally accepted doctrine on this point) it is assumed that except for some special cause acting upon the organism A, or its ancestors for each particular variation (v) of this kind, there would appear no deviation in B, there would arise no variety Bv. Let us be careful not to raise the question whether the organism could vary or could not; the question is purely regarding the order of the phenomena. It is a question of science as to whether the variation takes place on account of some cause (I use the word used by Darwin and suppose we may infer that he means some interference with the course of phenomena taking place in the developing organism), and I raise the question: Have we any evidence to support the opinion that variations would not occur except for some such interference with the normal processes of development exhibited by the growing individual?

If we examine Professor Cope's 'Primary Factors of Organic Evolution,' standing, as it does, for the most extreme of the Neo-Lamarckian school of naturalists as contrasted with the Darwinian, we find a similar assumption on this point. Cope divides

his treatise into three parts, which he enentitles: I. The Nature of Variation; II. The Causes of Variation; III. The Inheritance of Variation. He begins the Part III. by saying that he proposes to cite "examples of the direct modifying effect of external influences on the character of individual animals and plants. These influences fall naturally into two classes, viz., the physico-chemical (molecular) and the mechanical (molar). The modifications so presented are supposed to be the result of the action of the causes in question, continued throughout geological time" (p. 225). A few of the examples cited are the conversion of *Artemia salina*, a salt-water Crustacean into a *Branchinecta*, a genus accustomed to fresh-water habits; the production of colors in Lepidopterous pupæ; light and feeding affecting the color of fish; the case of the blindness of cave animals; Dr. Dall's theory of the origin of plaits in the Gastropoda; the moulding the shape of the articulation of bones in accordance with the dominant strain put upon them; the mechanical origin of dental types in Vertebrates.

No question is here raised as to the reality of the observed phenomena; the association of particular modifications of organic structure with change in the conditions of environment to which the organisms are subjected is not disputed. But the specific question raised is this: Does environment in general, or do the external influences of a chemico-physical or mechanical nature (to use Cope's phrases), exert an influence over growing organisms to induce them *to depart from* the order of phenomena of their ancestors, or do these influences or forces produce the opposite effect of *controlling and limiting* variation? From the quotations it will be evident that the theory is clearly expressed in the writing of the two prominent schools of evolution of to-day that *these external influences do, either directly or indirectly, produce the variations.*

Several years ago my studies led me to doubt the validity of this view, and a careful study of the order of sequence shown in the succession of species in geological time has confirmed this opinion. My friend and former neighbor, Professor Bailey, of Cornell, a pupil and ardent disciple of Asa Gray, has been led to the same conclusion from the study of plants, and he has supported and given botanical evidence for the validity of the theory in this book on 'The survival of the unlike' (Macmillan, 1896, see p. 21, 22). I also presented some evidence of paleontological nature which seems to support the view ('Geological Biology,' 1894'). The present paper is intended to consider the philosophical line of reasoning upon which the theory rests.

The commonly held conception seems to be that variation, and consequently the essential essence of evolution, is some kind of modification of ordinary generation. So much is this true that in most minds and in standard treatises on evolution the two words development and evolution are used as synonymous terms.

We may then resolve the question into this concrete form: In the case of any particular organic cycles of phenomena, is it more simple and fundamental for the organism to reproduce its kind or to produce itself, *i. e.*, its mature self from the germ? We can logically find but one reply to this question. Production must precede reproduction. But what does this answer imply? It implies that the processes of development of the individual from the germ to the adult do, in their intrinsic nature, precede the phenomena of reproduction. It further implies that the phenomena of evolutional variation are supplementary to, and then a further pushing on of, the phenomena of individual development. The assumption, which is generally accepted, appears to be that this mode of variation is a modification of ordinary reproduction, either produced

by some spontaneous action of the organism, or the result of the influence of changing environment upon the organism. For, in speaking of variation, it is customary to say that the variation becomes fixed by selection, or becomes transmitted, as if the disturbance in the order of the phenomena, which at first entered as an accident, became, by some means, an added part of the normal cycle of development of succeeding generations.

We hear such expressions as that it is impossible that a variation can be transmitted till it affects the germ-plasm, or till the variation becomes a variation of the reproducing, as distinct from the somatic, part of the individual. This conveys the impression that that which varies is the reproductive cycle of phenomena, whereas the truth is more accurately expressed by saying that the reproduction cycle is augmented. The augmentation in the case consisting of an extension of the process of growth of the individual beyond the point reached by the ancestor, the process is, first, purely of the nature of the building up of tissue and structure, and is not reproduction, but simple production, the process of production going beyond the extent or limit reached by the ancestors.

The confusion arises from not distinguishing the phenomena by which the structure of the individual is perfected from other phenomena by which a new individual becomes separated from the old and begins, carries on and repeats the previous cycle of phenomena. That phenomenon which is the first step of every evolutional process, as well as every step by which evolutional progress is accomplished, is fundamentally a growth phenomenon, quite of the same nature as the growth taking place throughout the life of each individual. It differs from these normal growth phenomena only by exceeding in some particular, or deviating in some manner, from the cycle of growth phenomena of the ancestors. Evolution does not call for any augmentation of the phenomena of reproduction.

If we separate the processes of (1) the growth or development of one individual from (2) the reproduction of a separate second individual we discover that the development of the first individual must necessarily have been carried to a certain point of completion before the reproduction of a germ takes place, since it is the more or less mature individual which reproduces the germ. When, further, we compare with these two processes the further phenomenon of variation which results in evolution we find that the variation does not belong to the reproduction, but to the development of the individual. Variation is a transcending the course of development of its ancestor by the offspring ; reproduction of the variation is not variation, but a repetition of a previous course of development. It is simply a continuation of those processes which have been going on in the individual and are regarded by the observer as perfectly normal up to the point of reproducing the features of the ancestor, but are looked upon as abnormal so soon as they transcend their limits.

Inquiry into what we mean by normal and abnormal will reveal the commonly received doctrine in the case. By normal we mean according to the steps of growth of the ancestor ; that is to say, the assumption is made that it is natural or normal for reproduction to proceed in some path already traversed. Now, in fact, this is not strictly true; first, we know that species are constantly showing departure or 'abnormal' growth (using abnormal in the above sense), and the deviation is called variation; and secondly, we have reason to believe that organisms never proceed in exact imitation of anything else, that every part of every organism is in some infini-

tesimal sense different from any other. This is really a distinctive feature of organisms as contrasted with bodies of inorganic matter.

This distinction between normal and abnormal reproduction, as if variation were but a slight modification of the so-called law of reproduction, has also led us into confusion. Reproduction is but the production again of what has been produced in a previous cycle; and a case of variation in the offspring, however slight, is not a case of reproduction, but of the production in the offspring of some new character, and the great thing to account for is the fact of the production of such new characters in organisms. But the process by which the individual acquired some new character is not different in nature from the process by which it acquired the old characters already expressed by its ancestors. If we can account for growth in the first place we are on the immediate track of accounting for the continuance of growth. To say that the growth of the individual in a particular direction and to a particular degree is due to the influence of the ancestor upon the offspring is offering a cause for reproduction, but not for variation; for, however variable the original stock might be, generation would result in increasing the degree of uniformity of the ancestry of each individual. As one can easily discover by computing the total number of direct ancestors of any individual with two parents, and supposing them to belong to distinct lines in each generation, it would take but twenty-one generations back to find one's lineage spreading over a million separate individuals of the twenty-first generation. If the ancestors controlled the growth of the offspring it is thus evident that, however different might be the individuals at any particular period in the course of a hundred generations, given free access to crossing, each offspring would unite strains of influence from every possible line of ancestry which had been accessible.

If variation were the result of difference in the external conditions, or what we call environment, the question arises why should not the same variability be expressed in the phenomena of crystallization; in the phenomena of chemical combination of elements; in the phenomena of light or heat, and in all the physico-chemical phenomena of matter, where like conditions produce like effects? If we have a uniform common force at work, the varying expressions of which are due to diverse conditions of environment, why should the result be so different from any other uniform common force operating under like diverse conditions of environment? The question brings its self-evident answer; the variations cannot be explained as the reflex of a discrete and varying environment upon a uniform common kind of matter. The idea that the cycles of development of the offspring should repeat the cycles of development of the ancestors is based on the prior assumption that the organism does not normally vary; that it acts as if it were an inorganic body, subject to the law of inertia and conservation of force. With this idea, it is easy to imagine that the cycle, once started, should not stop, except by reason of some resistance or impediment.

But we ask how can the cycle begin? How can it be started? and here we come to the fundamental point under consideration. Starting is itself variation—a departure from remaining inactive; and a cycle is uniformity, not variation. If the simplest act in the world takes place, it is a diversion from the condition of things before it took place; and if it stop and is simply repeated periodically, there is a cessation of the action of the initial starting force, and we have but the continuation of reflex action of the original impulse in the midst of resisting media. Hence, to begin

a cycle of phenomena, of whatever kind, requires the initiation of the original variation in which it began. The same is true of any variation thereafter, if we are to apply the reasoning which is valid regarding physico-chemical laws of matter to the phenomena of organisms. If the variation be primitive, and normal, to use the word in the sense proposed, it is evident that what we call reproduction is but a pulsation of the phenomena of life itself, recurring in the precise cycles which express the equilibrium between a definite quantitative force in the individual organism itself and the definite quantitative forces of the total environment in which it carries on its life functions.

The preservation and perpetuation of derived characteristics in a race seem at first sight to be easily accounted for by the process which Darwin has called natural selection. Variation, in this hypothesis, is supposed to occur 'naturally,' by accident, or, as Darwin says, 'spontaneously.' But a close examination of what such a proposition would mean in concrete facts reveals serious difficulties. The apparent simplicity arises from the assumption that the law of hereditary transmission of ancestral characters is a primary law of organism, which is violated in every case of variation. On such an assumption we have only to conceive of the removal of whatever may have occasioned the accidental or spontaneous disturbance in order to permit the continuing on of the normal working of heredity. But when we follow the hypothesis back to its beginning, it provides no means for rising from the original level of simplicity. Each variation must, according to the theory, be a violation of the normal action of the organism; hence if the organism were adjusted when the variation took place the variation puts it out of adjustment, and we have no place for the action of natural selection. If, on the other hand, the variation is advantageous to the economy of the organism, then we must assume either that the organism was not in perfect adjustment when it varied; and then again the adjustment is accounted for without the action of natural selection, or else the lack of adjustment came from change of conditions. In this case the conditions of environment, not natural selection, account for the adjustment. And there seems to be a still greater difficulty, viz., the extreme length of time necessary to bring about the changes that have taken place by the process. Recently Professor Poulton called attention to the necessity of this great time period (longer than the physicists or geologists are generally ready to allow to have been possible), in order to account for the results we find recorded in the fossil-bearing rocks, requiring at least 400 millions of years for the work of evolution.* But Mr. Poulton does not exaggerate the matter.

Let us examine this time factor and see if we can imagine it to have been long enough. In the first place, if hereditary repetition be the normal law of organism, then Professor Poulton has made a fair estimate of the ages it would take according to the present rate of evolution. But he has not taken into account all the necessities of the theory, two of which must be these: First, if the exact hereditary transmission and repetition be the fundamental law of organisms, not only must the progress produced by any mode of variation have been exceedingly slow—at first at a rate decreasing geometrically in proportion to the greater simplicity of the organism; but second, the theory requires that if natural selection consists in making variations permanent, the general progress must take place by means of a process which in every particular case consists in stopping the very phenomena by which the progress is at-

*Science, Vol. 54, p, 504.

tained. It is, moreover, this becoming permanent, by hereditary acquirement of the variation, which constitutes the evolutional progress of the series. And the difficulty we meet with is that we are assuming that natural selection must actually check, or even stop that variational activity by means of which any change whatever is attained, according to the theory of a primitive law of heredity. But if we were to grant that progress could be attained in this way, and allowing the slow rate of the actual process by which a variety becomes permanent enough to be called a strain or set habit of a race, and granting Professor Poulton's demand of the necessary four hundreds of millions of years for the process at the present rate—granting all this to be possible, we have still to reckon with a still more important process, the raising of the functional importance of the new varietal modification to reach a rank of specific, generic, family, ordinal, and, before we are through with it, class, branch and subkingdom value in the individual economy. The time required for this would be practically infinite. Because, with each step in advance in taxonomic rank and importance, the rigidity of transmission must be supposed to become greater, and thus the degree of possible variability diminishingly less. This would result, even if we were to grant that the change in taxonomic rank of the character be a fact.

But the evidences of paleontology go to disprove the very matter of fact. As has been already pointed out in another place, the degree of differentiation and the classification of invertebrates of the first great era in which we have definite records of organic life are so closely in conformity with that which we know of the invertebrates of the same classes now living that all the distinctions necessary to be considered in an ordinary course of lectures to a class of students in invertebrate zoology, to-day, would apply, so far as the facts are recorded, to the organisms which lived in the earliest period of which we have definite record of any living organism on the face of the earth ('Geological Biology,' p. 212). This evidence means that the same kind of characters, which are varietal and specific characters in living organisms to-day, were varietal and specific characters in the representatives of the same classes back in the Cambrian time; that the same kind of characters which are now generic in rank were then generic characters. And, so, in the case of family, ordinal and class characters we discover no trace of evidence that characters bearing a particular rank in the organic economy now, among living beings, did not always bear the same relative position among the characters of the bodies of their ancestors.

Attention was called to these facts several years ago and their validity does not appear to have been questioned. We observe, further, that in Cambrian time the differentiations of animals of branch value had already taken place, with the exception of vertebrates; and vertebrates appeared in the Ordovicean. And in the case of the vertebrates of the Ordovicean (and only a single locality for them is as yet known) their representatives are distributed by experts into three of the five known (*i. e.*, in fossil condition) sub-classes of Fishes. Fishes, it must be observed, include the type of vertebrates which are adjusted alone to an aqueous environment, and, therefore, we may conclude that, so far as the vertebrates of the environment of which we have any record for that era are concerned, they had reached over one-half the differentiation of sub-class rank ever attained by them.

Lest there should appear to be a misrepresentation of the opinions against which these arguments are directed, quotation from Darwin's 'Origin of Species' on

this point may appropriately be inserted here.

Darwin wrote:

"Hence I look at individual differences, though of small interest to the systematist, as of high importance for us, as being the first step toward such slight varieties as are barely thought worth recording in works on natural history. And I look at varieties which are in any degree more distinct and permanent as steps leading to more strongly marked and more permanent varieties; and at these latter as leading to sub-species and to species. * * * I attribute the passage of a variety from the state in which it differs very slightly from its parent to one in which it differs more, to the action of natural selection in accumulating difference of structure in certain definite directions. Hence I believe a well-marked variety may be justly called an incipient species (p. 53).

"Therefore, during the modification of the descendants of any one species, and during the incessant struggle of all species to increase in numbers, the more diversified their descendants become, the better will be their chance of succeeding in the battle of life. Thus the small differences distinguishing the varieties of the same species will steadily tend to increase till they come to equal the greater difference between species of the same genus, or even of distinct genera (p. 117).

"Natural selection acts, as we have seen, exclusively by the preservation and accumulation of variations, which are beneficial under the organic and inorganic conditions of life to which each creature is at each successive period exposed" (p. 117).

As if to make the inadequacy of this conception more apparent, we have but to look back across the geological ages, or, accepting the law of recapitulation, to trace the embryonic development of a single higher animal, in order to discover that the earlier differentiations were of actually higher rank, and that as time has progressed the new forms of organisms have been restricted to modifications of less and less importance. The earlier in time we go the more fundamental were the variations which took place, and it is in later geological times that there has come to be more and more rigid adherence to the law of heredity.

The proposed theory of original variability is not only consistent with such a series of events, but they would be the natural expression of such a force in operation. Variability should be most active and most vigorous before the laws of heredity had restricted its action. We must not, however, confuse activity of the operation of this law with multiplicity or complexity of activities in a common body. Complexity of structure is a matter of development and adjustment of the body itself, and much collateral evolution would be necessary before it would be possible for great complexity in a single body to be consistent with the limits of its vital functions. That the changes and adjustments would be great and rapid in proportion to those that followed when the adjustments had become close and involved is, however, evident. Hence it would be consistent to expect rapid evolution at first, gradually decreasing in rate with advance of time, as paleontology teaches us to believe was the actual fact of the case.

The difficulty in the commonly accepted view, it seems to the author, arises from mental confusion rather than neglect of the real phenomenon in the case. The mental juggling takes place when we speak of varieties or variation becoming more permanent, or when we speak of the preservation and accumulation of variations.

Variation as an act means becoming different, but variation as a thing means

something which does not vary. Permanent as an adjective means lasting and enduring, and thus it is contrasted with the adjective sense of the term variable. Thus when Darwin speaks of natural selection as acting by the 'preservation and accumulation of variations,' there is nothing variable in that which is conceived of as being preserved and accumulated. It is a character or morphological structure which is preserved and accumulated in the offspring only when it is the same character which appeared in the parent form. It is the fact of the reappearance of the same character in the offspring which is meant by its preservation. It will be seen, thus, that the origin, or arrival into the organic structure, of the particular concrete variation which, in any particular case, is transmitted and preserved must necessarily have taken place before natural selection acts in that particular case. Therefore, the variation, as an act, or the actual becoming different, is of a two-fold nature: (1) It consists, first, of the growth of some part of the structure of the organism in some way and degree differently from the growth of the same part in the ancestor; and (2), secondly, there is the reproduction of that difference in the offspring in accordance with the growth as it took place in the parent or immediate ancestor. Here, in the act, we see again a confusion of two acts, one of which is permanent and the other variable. The first act is a diversion or contradiction of the law of heredity, the second act is in conformity with it. The true variation, as an act, is thus a real departure, or diversion, from the phenomena of hereditary repetition. It is this which I understand Darwin assumed to have been spontaneous or constantly occurring, and it is the operation of natural selection, chiefly, and of other agencies working upon the living organisms, which, according to Darwin, results in the increasing diversity of the individuals. We are thus led by an analysis of Darwin's own theory to find that the real variations occur prior to any of those operations of the organism, or of the environment, commonly supposed to have caused them.

Darwin's theory, nevertheless, is readily adjusted to the conception of the fundamental nature of organic variation here proposed. It requires but an expansion of the idea of mutability of species so as to include mutability of the individual and of organic matter itself. Natural selection is constantly producing heredity, not variation. But natural selection is not the only cause; environment in general, and we might extend the idea of environment and say that experience is constantly resulting in the hereditary transmission of qualities or characteristics from parent to offspring.

The definite laws of heredity for any particular organism at any particular point in its history are but the recapitulation of the experience of its ancestors in overcoming, conquering and using for their enrichment the impediments and constantly acting hindrances to their living and existence. Varying is the first, as it is the last, performance of the living being. Invariability is the law of the inorganic world, but is the sign of death among organisms. This thought was aptly expressed by the late James D. Dana, in the last revision of his 'Manual of Geology.' Speaking of variation among organisms he wrote: "It is perceived that the law of nature here exemplified is not 'like produces like,' but like *with an increment* or some addition to the variation. Consequently, the law of nature, as regards the kingdoms of life is not permanence, but change, evolution" (p. 1033).

A rational and consistent conception of organic evolution arises from this theory of the fundamental nature of variation in organisms. Evolution is, to this theory, only the extension of the phenomena of

growth, or development of the individual beyond the point reached by its ancestors. Natural selection operates in the manner set forth in the current hypothesis, only the result is confined to holding in check and regulating the cycles of individual development, not to producing them. Environment affects the organism, both directly and indirectly, as Lamarck and the Neo-Lamarckians claim, but the effect is in the way of checking and then controlling variation.

The organism is in all respects dependent for its resources upon environment. Living is a constant process of occupying, using and discarding matter, and therefore any structure or function developed by the organic body is either profitable to the continuance of the living individual, or it is not profitable. Any modification of structure has a definite economic value to the individual; if its benefit does not equal its cost in energy its production is an unprofitable venture and is either not repeated or the individual is crippled and finally lost by the operation of natural selection. If the organism, for any cause, acquires surplus energy it is expressed in variation, and if the variation is to the advantage of the individual, *i. e.*, if the resources of new energy resulting from its presence exceed the expenditure for its construction and maintenance, the result is beneficial and the new structure is retained and a step in advance is made.

Thus the condition of environment, from the old point of view, seems to cause the organism to vary; in the new view, the organism adjusts and keeps adjusted to its environment by the law of internal economy, not by the external struggle for life.

It is not neeessary, here, to suppose that there must be a specific conscious adjuster residing in each organism. We do not find it necessary to imagine a specific *erdgeist* in order to cause the earth to follow the intricate curve of its revolution among the other planets and about the sun. Nor is it necessary to assume, as Professor Bailey puts it, that "definite variation is an inherent or necessary quality of organic matter,"* but given this general law of variation as an intrinsic property or mode of operation of every particle of living matter, and the phenomena of life will result—in the lowest stage as metabolic phenomena, then in the second stage as individual development and, also, in the third stage as evolution, by simply continuing their activities. And the same power which can constitute variation among the phenomena of matter, otherwise controlled by the inflexible physical laws of inertia and conservation of force, can, doubtless, institute in living matter that still higher function, consciousness, with all the wonderful phenomena which are associated with it.

The significance of this theory is considerable, both scientifically and philosophically. From a scientific point of view, variation or variability is recognized as the very essence of the vital phenomena, as gravitation is recognized as an essential characteristic of matter. Life is as remarkable (but perhaps no more so) as that sudden demonstration of expansion which inelastic water or rigid ice exhibits when raised to 212 degrees of Fahrenheit. We might study ice and water for eternity under temperatures below the boiling point and never discover the properties of steam So, whether the vital phenomena are latent in matter or not is a matter of speculation. Whenever vital phenomena appeared they appeared in phenomena exhibited by matter. Whenever inorganic matter becomes vitalized, however that result may be accomplished, variation takes place and distinguishes it from matter in every other condition.

*'The Survival of the Unlike,' p. 22.

If anything be evolved by evolution it is evident that, whatever its nature may be, it must cease to be evolved if it would maintain its integrity. For inertia of matter and conservation of force apply to bodies which no longer are undergoing evolution. Variation, as a process of becoming different, is a characteristic of living bodies, and, though it is not doubted that in the phenomena of variation it is ordinary chemical and physical matter which exhibits the peculiar vital phenomena, we have no reason to suppose that the operations of physics and chemistry are thus variable.

H. S. WILLIAMS.
YALE UNIVERSITY.

MICROSCOPICAL EXAMINATION OF WATER, WITH A DESCRIPTION OF A SIMPLE FORM OF APPARATUS.

THE microscopical examination of water is becoming every year a matter of greater interest, and the study of the minute aquatic plants and animals is more and more attracting the attention of scientists. These organisms are interesting for several reasons and, besides recognizing their importance in the domain of pure science, we are beginning to appreciate the great part that they play in nature and their effect, direct and indirect, upon the human being. Their presence in surface waters is often the cause of much harm when the water is used for purposes of domestic supply; scores of instances may be mentioned where they have rendered the water entirely unfit for use. On the other hand, their presence in ponds and streams is of importance to the fish-culturist because they form the fundamental source of the food supply of fishes; this is probably true both of salt and fresh water.

Because of this connection between the number of microscopical organisms in a cubic centimeter of water and the price of fish in our markets, the study of the 'plankton,' *i. e.*, the floating micro-organisms, is being emphasized on both sides of the Atlantic. Observers are beginning to trace the connection between the presence of microscopical organisms and the abundance of fish in our lakes, and valuable comparisons have been made between the stomach and intestinal contents of fishes and the organisms found in the water where the catches were made. This work is of very great importance and should be vigorously pursued by our fish commissions. To be of the greatest value it should extend well over the country and include lakes and ponds sufficiently different in character to enable one to determine the laws governing the nature and distribution of the plankton in various climates and under various conditions. The study ought not to be carried on spasmodically, as, for instance, during the short vacation of some college professor who generously gives his time and talents to the cause, but should be undertaken seriously and continued throughout the whole year. Only in this way can we obtain the data necessary for a complete understanding of the subject.

Since water works managers are equally interested in the microscopical organisms found in surface waters, and up to the present time have been responsible for most of the work done upon the subject, it might be possible for fish commissions, boards of health, water-works superintendents, and others interested, to work together according to a definite concerted plan, sending their results to some central commission or committee for comparison and study. Such an extended biological study taken in connection with meteorological records and observations upon the temperature, transparency, etc., of the water would be of very great value. And it would seem that we have little excuse for neglecting to cultivate this fruitful field of research. Vast num-

bers of microscopical examinations are now being made [during the past eight years more than 40,000 have been made in Massachusetts alone], and the rapid growth of the new science of sanitary biology is developing numbers of well-trained observers wide awake to the value of these problems and well able to undertake the work. What is needed is cooperation.

Various methods have been employed from time to time for determining the character and amount of microscopic life in water. Those interested in the subject from the piscatorial standpoint have usually employed some sort of net for straining the organisms from the water and concentrating them for the microscope. One of the best devices of this kind is that devised by Professor Reighard and used with good results for studying the plankton in Lake Michigan. It consists of a conical net of fine bolting cloth, at the small end of which there is a 'bucket,' made by covering a metal framework with some of the same bolting cloth. The apparatus is hauled through the water, filtering a column of water whose cross section is the same as the circular mouth of the net and whose length is equal to the distance through which the net is hauled. The organisms are caught by the fine bolting cloth and are ultimately washed into the bucket. The collected material is then removed by an ingenious arrangement, measured and sent to the laboratory for microscopical examination. By this method one is enabled to get a good idea of the total amount of suspended matter in the water, but it can hardly be called an accurate method of obtaining the number of living organisms present, as the net sweeps in amorphous matter as well as organisms and some of the smaller forms undoubtedly escape through the bolting cloth. Moreover, the amount of water actually filtered cannot be told with a great degree of accuracy. Nevertheless, the method is one of value, particularly for securing the larger and rarer forms of rotifers, crustacea, etc.

Sanitarians who have studied the microscopical organisms in water supplies have usually employed very different methods from the above, partly because they have been interested more especially in the smaller forms, but chiefly because their operations have been confined to the small quantities of water sent to the laboratories for analysis. During the last decade the old methods of sediment examination have given way to the filtration methods. The Sedgwick-Rafter method, which is most used at the present time in laboratories of water analysis, is carried on as follows:

A portion of the water to be examined is measured out in a graduate and filtered through a thin layer of quartz sand placed at the bottom of a glass funnel upon a perforated rubber stopper, the hole in which is capped with a disc of bolting cloth. When the water has filtered, the organisms will be found upon the sand, while the filtered water will be free from them. The rubber stopper is then removed and the sand washed into a test tube, with a measured quantity of distilled water delivered from a pipette. Usually 250 or 500 c. c. of the sample are filtered and the sand washed with 5 c. c. The test tube is then thoroughly shaken and the water decanted into a second tube; the organisms being lighter than the sand, will pass off with the water, leaving the sand clean upon the walls of the first tube. In this way the organisms are concentrated 50 or 100 times. One c. c. of this concentrated fluid is then transferred to a counting cell, which just holds it and which has a superficial area of 1,000 sq. mm. After putting a thin glass coverslip over this cell it is transferred to the stage of the microscope for examination. The eye-piece of the microscope is fitted with a micrometer in the shape of a ruled

square of such a size as to cover one sq. mm. on the stage, *i. e.*, one thousandth of the entire area of the cell. The organisms observed within the limits of the ruled square are then counted and the cell moved until another portion comes into view, when another count is made. Thus 10 or 20 squares are counted and the number of organisms present in the sample calculated.

This process has many things to be said in its favor, and it is undoubtedly the best all-around method for the study of the plankton. The apparatus required is simple, inexpensive and not liable to get out of order. The process is neither long nor difficult, and if care and cleanliness are observed in the manipulation very accurate results may be obtained. Ordinarily the quantity of water operated upon is small, but there is no reason why large filters may not be used. The writer has frequently used a funnel having a neck one inch in diameter, filtering from 1,000 to 10,000 c.c. This, when used with an aspirator to hasten the filtration, has given excellent satisfaction. The chief objection to the Sedgwick-Rafter method is that delicate organisms are liable to be crushed upon the sand, and this danger is naturally somewhat greater when this aspirator is used. It is probably no greater, however, than in Reighard's net.

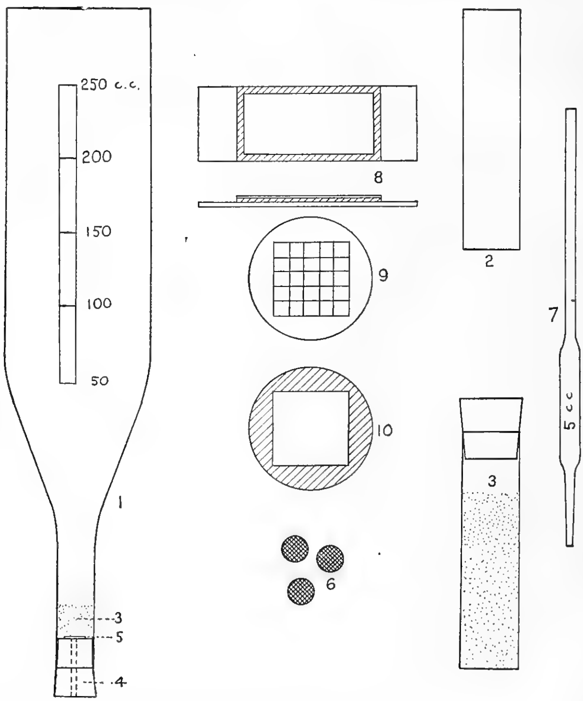
Recently a new apparatus has been devised for the study of the microscopical organisms, known as the planktonikrit. This is a modification of the centrifugal machine and depends upon the fact that the specific gravity of the organisms is different from that of water. It has the advantage of avoiding, to a certain degree, the crushing of the delicate infusoria, but it is somewhat inaccurate in the case of some of the lighter organisms; furthermore, it operates upon very small quantities of water.

In a complete study of the microscopical organisms, such as might be undertaken on cur great lakes, for example, it would be advisable to use all three methods, adopting the Sedgwick-Rafter method for general quantitative work, but using the net and centrifugal apparatus for determining the rare and delicate organisms.

As there are many lovers of the microscope who are interested in studying aquatic life, and as there are many others connected with water-works to whom the study of algæ and infusoria would be of much value, the writer has tried to reduce the Sedgwick-Rafter method to its simplest possible elements in order that it may be more generally used. Furthermore, it is often necessary for the sanitary biologist to be provided with a portable outfit for work in the field. There are many fragile organisms which will not bear transportation to the laboratory. Uroglena, for example, a very important and troublesome organism found in water supplies, goes to pieces completely when kept for a short time in a stoppered bottle. It is, therefore, necessary to make the examination of water immediately after the collection of the sample.

The chief modification of the method for field work consists in the use of a cylindrical glass funnel [Fig. 1] similar to the one designed by Mr. D. D. Jackson for the Massachusetts State Board of Health, but differing from it in having a capacity of 250 instead of 500 c.c., and in having graduations marked upon the sides. This funnel may be conveniently carried and its graduation renders the use of a second measuring glass unnecessary. When in use it may be supported on a wire frame, which any ingenious person can make. In place of the test-tube it has been found convenient to use tube vials [Fig. 2] having square ends. These require no racks and are not easily tipped over. The pipette for washing the sand might be dispensed with if one of the tube vials was graduated, but as much depends upon ac-

curacy in concentrating the sample it is best to use a short pipette [Fig. 7]. The sand [Fig. 3] used in the filter should be perfectly clean and of such size that its grains will pass through a sieve having 60 meshes to the inch, but not through one having 100 meshes. Crushed quartz makes the best filtering material and should be



used when obtainable. The discs of bolting cloth [Fig. 6] may be easily cut out with a wad cutter. The filtered water may be used for concentrating the organisms, or it is possible to employ preservative fluids in case the microscopical examination must be deferred or it is desired to keep the specimens. The cell [Fig. 8] for holding the concentrated fluid may be made by cementing a brass rim to an ordinary glass slip. It should be 50 mm. long, 20 wide and 1 mm. deep, thus holding just 1 c.c. and having a superficial area of 1,000 sq. mm.

A very simple microscope will answer for this work. A large stand is too valuable and too heavy for the rough usage in the field, and a cheap, light stand with a $\frac{1}{2}''$ or $\frac{2}{3}''$ objective and a No. 3 ocular will answer equally well. The ocular must be provided with a micrometer, so that the observer may count the number of organisms in one cu. mm. of the cell. A disc of glass ruled as in Fig. 9 is the best form of micrometer,

but a piece of thin metal with a square cut out, as shown in Fig. 10, may be substituted. In either case the square must be of such a size that it covers one sq. mm. on the stage with a given combination of objective and ocular, and a certain tube length to be found by comparison with a stage micrometer. It is an advantage to have at hand higher powers for a more thorough study of the organisms met with, but for ordinary work the powers suggested are sufficient.

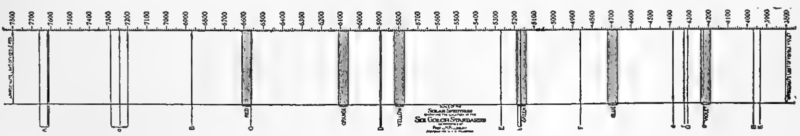
All this apparatus, together with bottles for collection and note book for records may be carried in a grip sack, and this will be found generally the most convenient way. It is possible, however, to make a neat box, with compartments for holding the microscope, funnels, tube vials, etc., and I respectfully submit this to manufacturers of microscopical supplies.

GEORGE C. WHIPPLE.

NEWTON CENTRE, MASS.

SPECTRUM COLOR STANDARDS.

THE extensive adoption of the *color standards* proposed by me and put into practical form for educational purposes by Mr. Milton Bradley, of Springfield, Mass., leads me to offer the readers of SCIENCE an opportunity to examine a chart of the solar spectrum after Rowland with the standard colors located upon it. The importance of making the spectrum the basis of all our work in color is recognized by all, and I have received many appreciative communications from eminent men in scientific and educational circles, both in this country and England, expressing approbation of the effort to bring our now greatly confused color nomenclature within some accurate and practical system. The idea of teaching color by a system thus definitely defined has also proved to be very practical, not only in elementary instruction, but in the more exacting art work. This rapidly increasing public interest in the subject makes it seem likely that the accompaning chart will be of interest.



A few observations on the practical application of these standards will illustrate the value of the scheme. The area representing each particular standard in the chart is narrow enough to allow of no perceptible difference in the hue of the two sides of the area when viewed through the spectroscope and is still wide enough to give a clear working field. Moreover, the areas selected coincide with the views of a large number of persons experienced in the discrimination of color and well prepared, therefore, to judge what would be of practical value as color standards and applicable to the various needs of the arts as well as to science and to educational purposes. And still again, though there was no direct reference to the theories of color vision, these standards having been first proposed nearly fifteen years since, the standards prove to have been happily selected as regards the more recent theories of color vision. Another very important consideration is the fact that the quality of any color which I have yet seen can be obtained by the union of two of these standards. Of course, the intensity of one of the two compared colors will generally have to be modified to obtain a perfect match, but I have never yet been unable to do this. In a

series of comparisons now before me, including many of the brilliant colors of silk ribbons recently so fashionable, I have had to reduce the intensity of the color to be reproduced, in only two out of sixty cases. This comparison was made by means of Maxwell discs made from the Bradley educational papers. For all practical purposes some form of paper or card board disc seems more convenient and proves quite satisfactory, as the above statement shows While it is possible to get somewhat more of brilliancy in silk than in pigment-covered papers, I have not found the increased brilliancy of sufficient value to compensate for the difficulty of making silk-covered discs that can be conveniently operated.

For educational purposes it seems to me of first importance that the child (and many adults are children in this regard) should start out with some clear and correct idea of a few pure spectrum colors. It does not matter essentially just how many of these colors he is taught, only that he gets a definite conception of those of which he learns. The reason for taking six for this series of standards was that I found that it was very difficult to get any practical scheme of color teaching based on a less number of standards. The mixing of two standards by means of the color wheel always reduces the strength of the resulting color. For example, the mixing of red and yellow on the wheel will produce orange, but it will not be as strong an orange as that of the standard paper. It will be a broken orange. Using the nomenclature adopted in my former articles (Science, February 26, '92, and June 9, '93) we have the result represented as follows: R 82 Y 18 gives the same effect as O 55 W 2 N 43. This can be best tested by using two sizes of discs. The larger should be compounded of red and yellow in the proportions just given and the smaller of orange, white and black as indicated. In this way the result is very satisfactory in fairly strong and pure diffused sunlight. The same principle will apply to all the colors of the spectrum. But the extent to which the effect of a broken color is produced will be increased, as the colors differ more widely in luminosity, or are more widely separated in the solar spectrum. Hence a smaller number of standards makes the practical use of the standards more difficult in the pupil's study of the colors by the use of the Maxwell discs. If we take a larger number of colors than six it becomes more difficult to designate them clearly in the solar spectrum, and the system becomes more complex. As there is quite general agreement that indigo shall not be used as a name for a spectrum color, the most natural and far the most convenient terms are those used in the scheme already referred to. When the pupil becomes familiar with these standard colors he is prepared to make very rapid progress in color study. The combination of these standards will give a ready appreciation of the nature of the purer color in objects about him and prepare the way for the analysis of colors, first those of a pure tone and afterwards of broken colors. The next stage would be the teaching of color harmonies. This most difficult part of the work becomes relatively easy by means of educational papers constructed on so simple a plan as this. It is surprising to see what results are obtained in the schools where this system has been followed.

It seems not inappropriate in this connection to call attention to an attempt to apply the principles upon which I have worked with a somewhat different set of standards from those I have used under the article 'spectrum' in the Standard Dictionary. In the first place there is no pure red used in the system, that called red being an orange red, as represented by the pigment vermilion. Nor is there any violet

used in the scheme, except by an unintended blunder, by which the wave-length of ultramarine is given as .4250, which would bring the standard blue designated into the clear violet of the spectrum and not distinguishable from the violet of my standards. The wave-length of ultramarine is not far from .4500. With no pure red or violet in a scheme of standard colors it is quite impossible to obtain or to represent accurately a very large line of important hues. The author of the article has been obliged, because of this defect in the standards he has selected, in many of the analyses of popular colors given in the table accompanying the article, to use three or four standards to represent the color he has analyzed where two pure spectrum colors are all that are needed. It is to be regretted that a publication like this should have added anything to the confusion which we are seeking to remedy. And this is still more to be regretted because the publishers of the Dictionary asked for and received from me the measurements and explanations of the plan upon which I had been working with the professed purpose of furthering the extension of the plan. This will not be as serious a matter, however, as it otherwise would have been, since the rapid introduction of the Bradley papers into the public schools gives an opportunity for the correct teaching of color to an enormous number of children.

J. H. PILLSBURY.

STONEHAM, MASS., June, '97.

PLEISTOCENE FOSSILS FROM BAFFINLAND AND GREENLAND.

THE existence of Pleistocene deposits in Labrador,* in several of the islands of the Arctic archipelago,† and in northern Greenland,‡ has been made known by several observers, but, so far as the writer is aware, none have previously been reported from Baffinland. The discovery of Pleistocene shells during the past summer on the south coast of Baffinland is, therefore, of interest as showing that at least a part of this island, which is the largest of the Arctic archipelago, was also affected by the subsidence which lowered the lands to the north and the south of it beneath the sea during the Pleistocene.

* Mem. Bost. Soc. Nat. Hist., Vol. 1, pp. 229–230.

† Jour. Geol. Soc., Vol. 9, p. 317.

‡ Jour. Geol. Soc., Vol. 3, p. 100.

Short trips were made into the interior by members of the Cornell University party from two points on the coast north of Hudson Strait. The first of these excursions was from a point opposite Big Island, in about long. 70 W., and the second some ten or twelve miles east of the first. At both localities Pleistocene shells were found in small lake basins a short distance from the coast at elevations from 100 to 200 feet above sea level. At two localities the shells were found in abundance, occurring in a fine blue clay mixed with some sand. These fossiliferous deposits do not occur in all of the basins and valleys, which are very numerous in this region. In most of them they appear to be absent.

The following is a list of the species arranged in the order of their abundance, which were obtained from a deposit of blue clay about 150 feet above sea level:* *Saxicava arctica*, *Mya truncata*, *Rhynchonella psittacea*, *Astarte compressa?* *Balanus crenatus*, *Pecten icelandicus*, *Lepeta cæca*.

In the interior of Big Island, Mr. T. L. Watson found Pleistocene shells at an elevation of 270 feet. The species which he obtained are *Mya truncata* and *Macoma subulosa*.

The Greenland shells are especially interesting because of the peculiar manner of

* The writer is indebted to Professor H. S. Williams for the use of specimens for comparison, and to Miss Katharine J. Bush for assistance in the determination of species.

their occurrence. All of them were obtained from the moraine fringing the margin of the ice cap along the base of the Nugsuak peninsula. The peninsula is a narrow mountainous tongue of land extending a little south of west from the mainland. Glaciers extend down to the fjiords from the ice cap on either side of the Nugsuak peninsula, while along its eastern base the ice cap terminates generally in a gently sloping margin, but sometimes in vertical cliffs forty to eighty feet high, which face small ponded lakes. From the Cornell glacier the margin of the ice cap rises gradually for a distance of four or five miles until it reaches an elevation of about six hundred feet, and then gradually descends again toward the glacier entering the fjord to the north. The morainal material, which occurs everywhere except at the lakes, just at the edge of the ice, was found to contain shells or fragments of shells up to the highest elevation which it attains, about 590 feet, at a distance of about four or five miles from the coast. At some of the small lakes the ice cliffs show distinctly stratified ice which carries an abundance of débris in the lower layers. Shell fragments were observed in the face of one of these cliffs at an elevation of 390 feet above sea level. Broken shells were also observed in the morainal material which has been dumped on the surface of the ice at a few points, owing to the sharp dip of the ice strata which brings the lower débris-carrying layers to the surface before they reach the outer margin of the melting ice.

The following species have been identified in the material collected from the moraine: *Saxicava arctica*, *Mya truncata*, *Macoma subulosa*, *Balanus crenatus*, *Yoldia* (*Portlandica*) *arctica*, *Cardium ciliatum*.

Many of the shells from the moraine near the fjord, which have evidently been carried but a short distance, have been handled in a surprisingly delicate manner by the ice. The *Macomias*, which are so fragile as scarcely to allow removal from the soft clay without crushing, have in many cases escaped from the ice without the slightest injury. The only specimen of *Yoldia* found still retained the epidermis, and the valves remained attached. In following the moraine back from the fjord toward the higher land which separates the Cornell and the Wyckoff glacial basins, the shells in the moraine become more and more fragmentary and broken as the irregularity of the land topography underlying the ice, and the distance which they have been transported, increases.

The occurrence of these shells in the moraine and in the ice makes it clear that they have been picked up by the ice from an old sea bottom which is now occupied by the ice cap. From the position of the shells and the direction of the ice flow which has transported them, the sea must have extended up the fjord when the shells were living at least four or five miles beyond the present face of the glacier. There seems to be only two possible interpretations of the relation of these shells to the ice. They either belong to a time previous to the beginning of extensive glaciation when the sea extended up the fjords as far as their slopes would permit, or they represent a retreat of the ice which allowed the sea to extend some miles up the fjord beyond its present limit, followed by a re-advance of the ice. If the former supposition be correct, the removal of shells must have been in progress from the beginning of glaciation in the region to the present time. It would seem that so long a period of excavation by the ice would have exhausted the material from so limited a supply. According to this theory, morainal material formed at an earlier period, when the ice extended beyond its present position, ought to contain shells as well as that now forming. I care-

fully examined such material for shells, but found no traces of them. These shells do not then belong to a preglacial fauna. The true interpretation of their history seems to be that there has been a retreat of the ice front some miles beyond its present position and a re-advance.

The remaining problem is, to what was the retreat and re-advance due, and when did it occur? The retreat was probably caused by the general subsidence in the north which is indicated by elevated deposits of recent shells in Baffinland, Grinnell Land and Labrador. A depression which amounted to 1,000 feet in Grinnell Land, and affected all or nearly all of the Arctic archipelago and probably Greenland, must have greatly increased the water area in the north and caused a corresponding rise of temperature. This rise of temperature would undoubtedly cause a retreat of the glaciers, permitting the sea to extend much farther up the fjords than at present, and in the shells which the ice cap is now carrying from the valleys of the interior we have proof that such a retreat occurred. With the elevation of the land in the north again, a lower temperature prevailed and the ice recovered some of its former territory.

E. M. KINDLE.

YALE UNIVERSITY, December 8, 1896.

CURRENT NOTES ON PHYSIOGRAPHY.

THE SIERRA NEVADA.

'FURTHER Contributions to the Geology of the Sierra Nevada,' by H. W. Turner (17th Ann. Rept. U. S. G. S., 1896, 521–1076) contain many geographical items. Oroville table mountain is illustrated in an excellent plate. The deep, steep-sided canyons that have been cut into the uplifted mass of the range often have benches on their slopes, caused by landslides; these, with the falls in the streams and the inaccessible character of the canyons, may be taken as features of a youthful stage of geographical development. Associated with them as indications of recent uplift are occasional fault scarps, still steep and bare; one of these being shown in a plate. Of a little greater age are the fault-block lake basins, now drained by filling with sediments and cutting down at the outlet; Meadow valley being of this class. Mohawk valley, first holding a Pliocene lake in a fault basin, was afterwards obstructed in Pleistocene time by fragmental andesite flows. Much of the volcanic material, once broadly spread over the Sierra area and now greatly dissected since its regional uplift, is shown to be fragmental, coarse and fine, less or more stratified; it is compared in origin to the mud flows of modern volcanoes. The flows came from the crest of the range, and ran for fifty miles on the comparatively gentle slope of the then low-lying region. The 'hog-wallow' mounds on the valley plain and margin of the foothills are described and illustrated, but not definitely explained; they are one or two feet high, four to ten feet in diameter, and of the same pebbly soil as that on the intervening spaces.

NORTH CAROLINA AND ITS RESOURCES.

'NORTH CAROLINA and its Resources' is the title of a volume published by the State Board of Agriculture (Raleigh, 1896, 413 p., many plates), to which the geographer may refer with profit. The mountains, with their minerals, mines, forests, and attractive 'resorts;' the piedmont belt, with rich fields and great water powers, the coastal plain with its growing interests in truck farms and orchards, and the sounds with their fisheries, are all duly set forth. This report forms a fitting companion to a volume on 'South Carolina, resources and population, institutions and industries,' published some years ago by the State Board of Agriculture (Charleston, 1882).

The latter lacks illustrations, but has a soil map.

DUNGENESS FORELAND.

Dr. F. P. Gulliver continues his studies on Cuspate Forelands (Bull. Geol. Soc. Amer. VII., 1896), by a study of Dungeness foreland, on the southeastern coast of England, one of the best examples of its class; having read his paper on this subject at the Liverpool meeting of the British Association in 1896 (London Geogr. Journ. IX., 1897, 536–546). He gives a restoration of the initial shore line of the region, and outlines of successive stages in the growth of the foreland, whose cusp has grown eastward and outward during its enlargement. It now projects about ten miles into the channel from the original reentrant of the coast; near the apex the shingle ridges or 'fulls' indicate the lines of progressive growth with much clearness. It is noted that English sailors have recognized forms in other parts of the world similar to this homė example, and have applied the home name to two widely separated forelands; one in Puget Sound, the other in the Strait of Magellan.

A FAULT LINE IN AFGHANISTAN

An account of the southern borderland of Afghanistan by Captain McMahon (London Geogr. Journ., IX., 1897, 392–415) includes a description of a remarkable fault line, along which the topography of a growing displacement is visible. It was examined for a distance of 120 miles, on an almost direct course a little east of north, near the southeastern corner of Afghanistan; a well defined broad line of deep indentation, in many places as distinct as a deep railway cutting. It ran for a time along the border of the Registan plains, then obliquely traversed two mountain ranges, cutting the crest of one near its highest peak. Springs are common along it, and for this reason as well as because it forms a short cut across mountain spurs, the depression is commonly used as a thoroughfare. Igneous rocks form the country to the west, and sedimentaries lie to the east of the fault line. During the lifetime of the older natives, on the occasion of three severe earthquakes, deep fissures appeared along the depression, and the springs increased in volume. The line crosses a frontier railway near Chaman, beyond Quetta. A severe earthquake on December 20, 1892, opened a fissure where the fault crossed the track, distorting the rails, and lessening the distance between Quetta and Chaman by 2½ feet. All the region is desert—bold, barren mountains, stony slopes, shifting dunes, alluvial and saline plains; many camels died in McMahon's trip across it.

W. M. Davis.

Harvard University.

SCIENTIFIC NOTES AND NEWS.

Professor Alfred M. Mayer, the eminent physicist, died at Maplewood, N. J., on July 13th, aged sixty-one years.

On the recommendation of Hon. Chas. D. Walcott, acting Assistant Secretary of the Smithsonian Institution, in charge of the U. S. National Museum, an important change has been made in the administration of the Museum. Three sections have been organized—a section of anthropology, a section of biology and a section of geology, each having a head curator with an annual salary of $3,500. Dr. W. H. Holmes has been appointed head curator of anthropology; Dr. Frederick W. True, head curator of biology, and Dr. George P. Merrill, head curator of geology. Dr. True and Dr. Merrill are already connected with the Museum, and it is expected that Dr. True will continue to act as the executive curator. Dr. Holmes leaves the Field Columbian Museum, Chicago, to accept this position, but was formerly connected with the U. S. Geological Survey and the Bureau of Ethnology.

The Berlin Academy of Sciences made, at its last meeting, awards for scientific purposes

amounting to nearly $20,000. These awards were as follows: To Professor F. E. Schültze for the publication of *Das Tierreich* under the auspices of the Zoological Society, 35,000 M.; for the publication of the new edition of Kant's works, 25,000 M.; to Professor Engler for the publication of monographs on African botany, 2,000 M.; to Dr. G. Lindau for studies on Lichens, 900 M.; to Professor F. Frech for his geological studies, 1,500 M.; to Professor H. Hürthle for studies on muscles, 850 M.; to Professor R. Bonnet, for the preparation of a work on blood vessels, 800 M.; to Dr. Lühe, for investigations of the fauna of salt lakes of North Africa, 2,000 M.; to Dr. G. Brandes, for studies on Nemertina, 300 M.; to Dr. R. Hesse for investigations at Naples on the eyes of lower marine animals, 500 M.; to Professor E. Cohen for investigations of meteorites, 1,500 M., and to Dr. L. Wulff for experiments on artificial crystals, 1,500 M.

THE Academy of Sciences of Vienna celebrated, on May 30th, the fiftieth anniversary of its foundation. The government made this the occasion of increasing the annual subsidy of the Academy from 40,000 to 50,000 Fl.

THE German Zoological Society held its seventh annual meeting from the 9th to the 11th of June at Kiel. We learn from *Die Natur* that the program we have already announced was carried out, except that the president, Professor Bütschli, was unable to be present and the meeting was presided over by Professor J. B. Carus. There were thirty-seven members and thirteen guests in attendance. It was decided to hold the next annual meeting at Heidelberg at Whitsuntide.

THE eightieth meeting of the Swiss Scientific Association will be held at Engelberg from the 12th to the 15th of September. The place of meeting is in the midst of fine Alpine scenery a three and a-half hours' drive from the nearest railway station. American men of science are cordially invited to be present.

THE Anatomical Society, intended to be international in character, but chiefly supported by German anatomists, held its eleventh meeting at Genth from the 24th to the 27th of April, with fifty members and guests in attendance. The President, Professor Waldeyer, discussed anatomical nomenclature, and papers were presented by Professor O. Schültze, Professor v. Kölliker, Professor v. Bardeleben and others. The next meeting will be held at Kiel during April of next year.

THE preliminary program of the first International Congress of Mathematicians, to be held at Zurich from the 9th to the 11th of August, announces that in addition to two general meetings there will be six sectional meetings as follows: Arithmetic and algebra, analysis and theory of functions, geometry, mechanics and mathematical physics, astronomy and geodesy, history and bibliography. At the general sessions the following papers will be presented: 'On the relations between pure analysis and mathematical physics,' by Professor H. Poincaré; 'On the recent development of the general theory of analytical functions,' by Professor A. Huritz; 'On the teaching of higher mathematics,' by Professor F. Klein; On *Logica Mathematica*, by Professor G. Peano. The dues for the Congress are 25 fr., which sum includes the cost of the banquet and other entertainments.

THE second of the annual conversaziones of the Royal Society was held on June 16th. Demonstrations with illustrations were made by Mr. W. H. Preece on signalling through space without wires, and by Professor Lockyer on the arrangements of the 1896 eclipse expeditions. There were exhibits by Lord Kelvin of the electrical effects of uranium and of X-rays, by Professor S. P. Thompson, Mr. A. A. C. Swinton, Dr. John Macintyre, Dr. J. H. Gladstone and Mr. Walter Hibbert. There were also other interesting exhibits, both in the biological and in the physical sciences.

THE annual field meeting of the Indiana Academy of Science was held at Lafayette from the 26th to the 28th of May, with an attendance of forty members. Excursions were made in the surrounding regions, and an address was given by Professor Frederick Starr, his subject being 'Dress and Ornament.'

PROFESSOR A. C. GREENHILL, of Woolwich; Professor J. V. Jones, of Cardiff, and Professors John Perry and W. E. Ayrton, of London, have expressed their intention of being present at

the Detroit meeting of the A.A.A.S. and participating in the proceedings of the section for physics.

THE Albert medal of the Society of Arts, London, has been awarded to Mr. G. J. Symons for his services to meteorology.

THE Senckenberg Society of Natural History at Frankfort has awarded the Sommering prize, consisting of a medal and 500 M., to Professor Gustav Born, of Breslau, for his researches on the growth of the larvæ of amphibia.

THE death is announced of Dr. P. Schützenberger, professor of chemistry at the Collège de France, at the age of sixty-seven years. He had been since 1888 member of the Paris Academy of Sciences and had made important contributions to organic chemistry.

WE also regret to announce the following deaths: Dr. Alfred Moquart, professor of anatomy at Brussels, on June 5th; Professor Martin Wilckens, of the Agricultural School of Vienna, on June 10th, at the age of sixty-four years; Count Victor Trevisan di S. Leon, the cryptogamist, in Milan, on April 8th, and Frau Dr. Vera Bogdanowskaja-Popoff, on May 8th, as the result of an explosion while carrying on chemical experiments.

DURING the Moscow meeting of the International Medical Congress a statue to the eminent surgeon Pirogof will be unveiled. The sum of 12,000 roubles (about $6,000) has been collected by public subscription for the statue, the sculptor of which is Mr. V. R. Sherwood.

M. HATT and Professor de Lapparent have been elected members of the Paris Academy of Sciences.

MR. F. D. GODMAN has been elected President of the British Ornithologists' Union.

PROFESSOR P. ROUSSELOT, of the École des Hautes Études, Paris, has been appointed director of the laboratory for experimental phonetics, the establishment of which under the Collège de France we recently announced.

MR. HENRY L. BRYAN has been appointed, by the trustees of the Philadelphia Commercial Museum, Secretary of the Museum.

THE U. S. Civil Service Commission announces a competitive examination, on August 9th, for the purpose of establishing a register from which certification may be made to the position of Examiner, Mint Bureau, Treasury Department, at a salary of $2,500 per annum. The duties of the position comprise the inspection and supervision of all the machinery installed in different U. S. mints throughout the country. Applicants should be graduates of recognized technical schools giving courses in mechanical engineering, or should, in lieu of this, have very broad training and experience along the lines of mechanical engineering.

PRESIDENT JORDAN has passed through Seattle on his way to Alaska. He is accompanied by Professor Wood, of Stanford University.

MR. H. W. TURNER, of the U. S. Geological Survey, and Professor John C. Branner, of Stanford University, are engaged in exploring in the region of the Yosemite and Hetch-hetchy Valleys and the adjacent mountains.

MR. R. W. PORTER and Mr. A. V. Shand, who are accompanying Lieut. Peary on his present expedition, expect to spend the winter in Baffin Land making ethnological and zoological studies and collections. They expect, in the summer of 1898, to explore the country northward and to return on a whaling ship from Cumberland Sound to Aberdeen.

THE men of science who will embark on the 'Belgica' on its approaching expedition to the Antarctic regions will be as follows: The captain, M. A. de Gerlache, geology, meteorology and oceanography; M. Arctowski, terrestrial magnetism and physics; M. Danes, zoology, and M. Racovitza. The crew have already embarked in Norway and it is expected that the steamship will leave Antwerp on the 25th of the present month. The men of science expect to spend the Antarctic winter in Victoria Land, while the steamship will go to Melbourne to renew its stores.

PROFESSOR F. A. STARR has returned to the University of Chicago, from an expedition to New Mexico, having explored one of the mesas and one of the caves of the Cochitas, and having secured plaster casts of the busts of a number of Pueblo Indians.

THE Canadian Pacific Railway Company will sell first-class return tickets to members of the British Association from Toronto to the Pacific Coast, at a rate varying between $61.80 and $70.30, according to the route selected. This is less than a single fare and the tickets are available from July 1st to October 1st.

DARWIN'S family have presented to Cambridge University the geological specimens found during the voyage of the 'Beagle' and a series of slides used in the preparation of his monograph on the Cirripedia. The former has been placed in the Museum of Geology, the latter in the Museum of Zoology.

IN celebration of the Cabot quatercentenary the foundation stone of a memorial tower to be erected on Brandon Hill, Bristol, was laid on June 25th. The tower will be 100 feet in height, squarely built with emblematic panels. Some of the bas-reliefs will be contributed by an American committee, the President of which is Mr. Bayard, lately Ambassador to Great Britain. Lord Dufferin made a speech describing what little is known of Cabot and the adventurous voyage of the 'Matthew' and its importance for the extension of Anglo-Saxon civilization.

THE Geological Society of Portugal opened on July 8th the new Geographical Institute founded at Lisbon in commemoration of the 400th anniversary of Vasco da Gama's departure for the Indies.

THE Academy of Medicine of Paris has received a legacy of 15,000 fr. from Mme. Clarens for the foundation of an annual prize.

THE scientific library of the late Sir G. Humphrey, professor of surgery at Cambridge, has been presented by Mrs. Humphrey to the surgical department of the University.

THE town of Middletown, N. Y., receives, by the will of the late Mrs. S. Maretta Thrall, $30,000 for a public library. She had already given the town a hospital and a park, the value of her gifts aggregating $80,000.

THE Board of Education of the City of New York has adopted a resolution providing for the employment of oculists to report upon the best colors to be used in painting and decorating schoolrooms with reference to their effects on the eyesight of children.

REPRESENTATIVE LACEY, of Iowa, has introduced a bill in the House of Representatives providing that the name of the Fish Commission shall be changed to the Commission of Fish, Fisheries and Birds. It is proposed that the Commission shall extend its jurisdiction to provide for the propagation, distribution and restoration of game and other wild birds of the United States. It is not likely that this change will be made, as wild birds and mammals are already provided for under the Department of Agriculture, and any extension of the work should be developed under that Department.

BEGINNING with the number for July, the *Physical Review* will be published by the Macmillan Company in two volumes annually. These volumes will begin in January and July respectively, and will each contain about five numbers.

Natural Science for July, now published by J. M. Dent & Co., and printed by Turnbull & Spears with improved typography and better paper, contains articles by Professor Bashford Dean on the Hopkins Seaside Laboratory of Stanford University, and by Dr. P. L. Sclater on 'The Proposed Zoological Park in New York.' *Natural Science* should have given credit to *Nature* for the queer note to the effect that Professor Putnam and Dr. Boas have started on a six years' expedition to study the relation of the American Races to those of Asia and Africa. "They will proceed up the northwest coast of North America, cross Behring Strait, and so pass down through eastern Siberia into China, and thence along the Indian Ocean to Egypt."

THE presidential address by Dr. G. W. Hill before the American Mathematical Society in 1895, printed in the issue of this JOURNAL for March 6, 1896, is published in the current number of the *Revue Scientifique*. It is credited as a presidential address before *l'Association scientifique americaine.*

PROFESSOR RÖNTGEN has contributed to the *Berichte* of the Berlin Academy an account of further observations on the properties of the X-rays. He has observed that the rays emanate from the irradiated air in all directions so

that if the rays were visible the appearance would be that of a room filled with smoke and lighted up by a candle. When a plate impervious to the rays is placed between a fluorescent screen and a source of the rays the platinocyanide of barium nevertheless becomes luminous, and this luminosity is visible even when the screen lies directly upon the plate. If, however, the screen placed on the plate is covered by a cylinder of lead 0.1 cm. in thickness surrounding the fluorescent screen the fluorescence disappears. Professor Röntgen has further been able to measure the intensity of the rays and to study the influences on which this depends. Dr. Brandes' observations that the X-rays may be made visible, presumably by causing fluorescence of the retina, are confirmed. Professor Röntgen sums up the present state of our knowledge in regard to the rays as follows: (1) The rays proceeding from the discharging apparatus are a mixture of rays varyin absorbability and intensity. (2) The composition depends chiefly on the duration of the discharging current. (3) Different bodies absorb different kinds of rays. (4) The X-rays are produced by the cathode rays and the phenomena of both are probably of the same nature.

THE compilation of the statistics of coal production in the United States in 1896, which has just been completed by Statistician E. W. Parker, of the U. S. Geological Survey, shows that the product in 1896 was 190,639,959 short tons, valued at $195,557,649, against 193,117,530 short tons, valued at $197,799,043 in 1895, a decrease of 2,477,571 short tons in amount, and of $2,241,394 in value. The decrease in product was entirely in that of Pennsylvania anthracite. The output of bituminous coal shows an increase of about one and three-quarters million tons. The anthracite product of Pennsylvania decreased nearly four and a quarter million tons. It is a notable feature, however, that there was a decrease in the value of the bituminous product of over $1,600,000, notwithstanding the increased output, and that there was a comparative increase in the value of anthracite, although, on account of the smaller production, it did not equal the value in 1895. The average price obtained for anthracite at the mines increased from $1.41 in 1895 to $1.51 in 1896. The average price for bituminous declined from 86 cents to 83 cents.

AT the coming International Leprosy Conference, to be held in Berlin on October 11th, Dr. Hutchinson, of London, will report on alimentation and leprosy; Professor Virchow on the pathological anatomy of leprosy; Dr. Neisser, of Breslau, on its origin; Dr. Bernier, of Paris, on its etiology, and Professor Koch will discuss the question of its infectiousness.

WE learn from *Natural Science* that the Natural History Museum of Halifax, which was handed over to the County Borough Council about eighteen months ago by the Literary and Philosophical Society, has now found a permanent home in the old mansion named Belle Vue. The geological and botanical collections are very extensive and valuable, but zoology is as yet very imperfectly represented. The herbarium has lately been much enriched by the fine Gibson collection of British plants, the gift of Lady Trevelyan. The Curator, Mr. Arthur Crabtree, is making an attempt to render the Museum of general educational value by adequate labelling, and wishes to secure a competent committee of management to direct and second his efforts.

UNIVERSITY AND EDUCATIONAL NEWS.

THE Supreme Court of New York State issued on July 6th its final decision in the Fayerweather will case. The executors were required to distribute within ten days the three million dollars in question to the twenty colleges to which they were bequeathed.

THE only colleges so far as we have noticed which have this year given the Ph. D. degree *causa honoris* are Union, Dartmouth and Tufts. These colleges have acted unwisely and Union College, as we understand it, illegally.

PROFESSOR WILLIAM A. ROGERS, who recently accepted the Babcock professorship of physics in Alfred University at Alfred, N. Y., delivered the principal address at the laying of the cornerstone of the Babcock Hall of Physics at Alfred on June 22d. The hall is named after the late George H. Babcock, of Plainfield, N. J., who left $100,000 to Alfred University.

AT the University of Indiana A. L. Foley, Ph. D. (Cornell), has been elected professor of physics; R. J. Aley, Ph. D. (Pennsylvania), professor of mathematics; E. B. Copeland, of the University of Wisconsin, assistant professor of botany, and E. B. Bryan, assistant professor of pedagogy.

HENRY C. MINTON, of San Francisco, was elected President of Centre College this week.

DR. G. J. PIERCE has been elected assistant professor of botany in Stanford University.

IN the newly organized high schools of New York City, as the result of a competitive examination, there have been appointed as first assistants, at a salary of $3000, Mr. Frank Rollins, chemistry; Mr. R. H. Cornish, physics, and Mr. E. W. Sampson, physical geography.

THE University of Strasburg has celebrated, by fêtes lasting several days, the 25th anniversary of its foundation.

PROFESSOR W. TH. ENGELMANN, of the University of Utrecht, has been offered the chair of physiology at Berlin, vacant by the death of Du Bois-Reymond, but it is stated that he will not accept. The position had previously been twice declined.

DR. JAEGER and Dr. Brodhun have been appointed professors at The Reichsanstalt at Charlottenburg; Dr. Ignaz Zakezewski has been made full professor of experimental physics at the University at Lemburg, and Dr. H. Finger, of Giessen, has been appointed assistant professor of organic chemistry at the Polytechnic Institute in Darmstadt.

DISCUSSION AND CORRESPONDENCE.

A BRILLIANT METEOR.

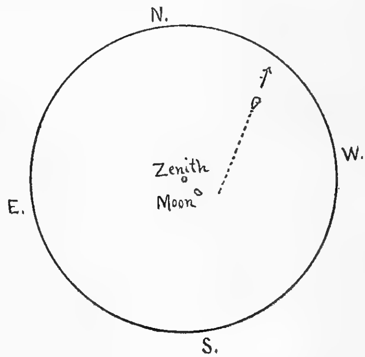
TO THE EDITOR OF SCIENCE: On June 22d a brilliant meteor was observed in broad daylight passing over Cape Breton Island, Nova Scotia. In order that some permanent record of the fact may exist, I beg to forward for publication a letter received from Mr. George Kennan, who was an eye-witness of the occurrence.

ALEXANDER GRAHAM BELL.

BEINN BHREAGH, NEAR BADDECK, C. B., NOVA SCOTIA, July 1, 1897.

Letter from Mr. George Kennan.

MY DEAR MR. BELL: I will gladly give you all the information I can in regard to the meteor. Between half-past eight and nine o'clock, Tuesday morning, June 22d, as I was going into my garden to work, a very large and extraordinarily bright meteor suddenly made its appearance nearly southwest of the zenith, at a height of about 70 degrees from the horizon and almost directly under the old waning moon. I happened at that time to be looking upward and westward, and I think I saw it at its place of origin—that is, at the point where it first became visible. It was not a mere point of light, like a brilliant star, but seemed to have a large, well-defined disc, resembling in shape a somewhat elongated and almost inverted balloon with its top or larger end foremost—that is, turned in the direction of its fall. It came into



the field of vision so near the waning moon that I was able to compare the one with the other in point of size, and the impression made upon my mind was that the disc of the meteor was nearly as large as the filled-out circle of the moon would have been. Of course, the eye unconsciously exaggerates the size of a brilliant object, and it probably did so in this case, but such was the impression made upon me, and I give it for what it may be worth. I don't think the meteor had any decided color. At any rate, all that I noticed was its extraordinary brilliancy. If it had been decidedly green, red,

or yellow, I think I should have become conscious of the fact. It seemed to be followed by a faint line of light about half as long as its own body. From a point about 20 degrees southwest of the zenith it fell rather swiftly in a direction that would have brought it to the horizon at a point very nearly northwest (magnetic) of my position. I was unable, however, to follow it all the way to the horizon on account of the trees between my house and your cottage behind which it disappeared without having lost either its shape or its brightness. The time occupied by its fall was not more, I think, than three seconds. If you will hold the accompanying diagram above your head like a celestial chart and look up at it, facing the west, you will get an approximate idea of of the meteor's course as it appeared to me. The sun was shining brightly, but it did not overcome the brilliancy of the aerolite.

Sincerely yours,

GEORGE KENNAN.

BRETON COTTAGE, BADDECK, C. B.,
NOVA SCOTIA, June 26, 1897.

SCIENTIFIC LITERATURE.

WHAT ARE STIPULES?

'THE Nature and Origin of Stipules,' by A. A. Tyler, A. M. Presented to the Faculty of Pure Science of Columbia University in partial requirement for the degree of Doctor of Philosophy. Annals of the New York Academy of Sciences, Vol. X., New York, 1897, pp. 1–49, pl. i.–iii. Also separate: Contributions from the Department of Botany of Columbia University, No. 119.

This is, without doubt, the most considerable contribution that has been made to the vexed question of the nature of stipules; at least it is safe to say that it comes much nearer to a solution of that question than anything that has hitherto been brought forward. Although assuredly not the last word that will be said on the subject, nevertheless the light that had already been shed upon it by a long train of previous investigations placed the author in a position to treat it from an advanced standpoint.

Nearly half the paper, and that the first half, is devoted to summing up, in chronological order, the views that have been expressed and the conclusions that have been reached; but the paper is by no means a mere literary effort. It is itself the result of a series of special researches on the part of the author. Indeed, it may be looked upon as a new departure, since his investigations have proceeded from an almost entirely different standpoint from those of previous authors. He has made use of their labors and failures rather as a means of warning than as guides to his work.

Probably the most suggestive results that had been reached were those which, within the past decade, have been furnished by paleontology, and while he has singularly omitted to mention the researches of Saporta and Marion,* he has not left out of account those that have been made in America.† It is not too much to say that these paleontological discoveries have added more to our acquaintance with the true nature of stipules than the combined morphological studies of previous authors. If I do not mistake, it was from attention to paleontological considerations as thus brought out, that Mr. Tyler was led to adopt the method of his thesis, a method which had been wholly neglected hitherto, and yet the only one that seems to promise ultimate success in the solution of the problem.

The earliest of the above mentioned papers called attention to certain remarkable basilar expansions that occur in leaves of *Platanus basilobata*, a fossil species from the Fort Union

* Evolution du Règne Végétal, Pt. II., Phanérogames. Paris, 1885. See especially Vol. I., pp. 201–223; Vol. II., pp. 9–44.

† The Paleontologic History of the Genus Platanus by Lester F. Ward; Proc. U. S. Nat. Mus., Vol. XI., 1888, pp. 39–42, pl. xvii.–xxii. Origin of the Plane-Trees, by Lester F. Ward; Am. Nat., Vol. XXIV., September, 1890, pp. 797–810, pl. xxviii. Flora of the Dakota Group, by Leo Lesquereux; Monogr. U. S. Geol. Surv., Vol. XVII., pp. 65, 231, 232, 254. Wing-like Appendages on the Petioles of *Liriophyllum populoides* Lesq. and *Liriodendron alatum* Newb., with Descriptions of the Latter, by Arthur Hollick; Bull. Torr. Bot. Club, Vol. XXI., No. 11, November 24, 1894, pp. 467–471, pl. ccxx., ccxxi. Appendages to the Petioles of Liriodendra, by Arthur Hollick; Bull. Torr. Bot. Club, Vol. XXIII., No. 6, June, 1896, pp. 249–250, pl. cclxix., cclxx.

group, which was compared with another fossil species, *P. appendiculata* of Lesquereux, in which somewhat similar basilar expansions occur, but in this case separate from the main blade. The latter species comes from the Auriferous gravels of California, a much later formation, and it was argued that these two cases indicate a gradual separation of these lobes from the blade as having taken place in the progress of development. It was further shown that the living American species, *P. occidentalis*, sometimes has a small expansion at the base, through which the petiole passes, and that other cases may be found on young shoots in which these lobes are distinct from the blade.

The second paper cited, though chiefly a criticism of a memoir by Jankó, on the leaves of Platanus, discusses the subject of basilar expansions with additional illustrations.

Dr. Hollick's papers deal with an almost similar condition of things in the fossil species of Liriodendron. Both of these genera belong to what are known as waning types, and their present foliage has reached its highest state of development.

These and other facts that have been from time to time coming to light had begun to imbue botanists who had given attention to the subject with the general idea that stipules are morphologically portions of the leaf that have been gradually separated from the existing leaf blade through a process of development going on under the influence of the great principle of advantage in biology, which relegates to the domain of vestiges or obsolescent organs everything that has ceased to benefit the organism, a process which has as its ultimate result the complete extinction of such organs, and there is no doubt that in many cases modern exstipulate leaves have once had stipules and lost them, although it is also true, as Mr. Tyler shows, that in other cases, especially those of sessile leaves, no stipules have ever existed.

In 1894 Mr. Morong, in treating the genus Smilax,* said: "Most of the species climb upon other shrubs and trees by means of a pair of tendrils which grow at the summit of a stipular wing on each side of the petiole, often not developing till the stem is several years of age;" to which he adds in a footnote: "De Candolle regards this appendage as more in the nature of a modified leaf segment or leaflet than a stipule, but it seems to me that a stipule is nothing else than a leaflet at the base of a petiole." Mr. Tyler does not note this statement of Mr. Morong in his bibliographic summary, but it is characteristic both of Mr. Morong's keen insight into such matters and also of the general drift of botanical thought on the subject.

* Bull. Torr. Bot. Club, Vol. XXI., No. 9, September 29, 1894, p. 420.

In the paper before us there are brought out into clear light at least three distinct and highly important facts. The first relates to method. It had long been felt that the great need in botany was the study of plants from the embryological standpoint in some such way as animals have been studied with such remarkable results. The two great sources of our knowledge of development in both kingdoms are, first, paleontology, and second, embryology. Both of these had been almost totally neglected by botanists until within recent years. Something, it is true, had been done along the more general lines of plant development from the paleontological side, but scarcely anything in connection with the transformation that leaves undergo, and the few papers above quoted constitute practically all that has been done in this line. A number of attempts have, however, been made to approach the vegetable kingdom from the embryological point of view. But the seed being regarded in a certain sense as the homologue of the egg, most of these attempts have been devoted to the study of the seed and of seedlings, the great work of Sir John Lubbock constituting the most exhaustive of these efforts.

Mr. Tyler has shown in the present paper that the study of plant embryology should not proceed from a consideration of seeds and their development, but of buds, and that while botanists have been mainly seeking for light in the difficult study of seed embryos, the true source of such knowledge is the much more accessible phenomena of bud development. The figures that he has given abundantly demonstrate this truth, and henceforth there can be no doubt that botanists generally will proceed according to this method and that the

natural history of the leaf will soon be fully known.

The second lesson which Mr. Tyler's paper enforces is the one which paleontology, as we have seen, had already taught. What the leaf struggles to secure is the maximum amount of light and air. In this effort it constantly tends to stretch out as far a possible from the stem. The proximal portion, which is most shaded, is then sacrificed to the distal portion, and the leaf is differentiated into petiole and blade. But in this process various stages occur. Those parts which are of any advantage to the plant are in part retained, and the parts sacrificed are selected in the exact measure of their failure to benefit the plant.

Some may regard the principle of adaptation for securing the maximum light and air as inadequate to explain these modifications of the leaf, but it is this principle that determines not only the form but also the arrangement of leaves, and when we remember that opposite leaves are also decussate, that in whorled leaves those of one whorl stand over the intervals between those of the next whorl below, and that even in plants with alternate leaves the phyllotaxy is so adjusted as to secure the longest interval between one leaf and the next one that must stand directly over it, we not only see with what rigorous exactness this principle works, but also what apparently trifling differences in advantageousness are seized upon and made to count in producing manifest effects.

The least useful portion of a leaf is not that at the very base, but that which is some distance from the base, and even this may be partially retained as a wing to strengthen the leafstalk. The portion at the base is often preserved in one form or another, and we have seen, in the fossil and living species considered, how this may vary in the process of evolution, but in the most highly developed of our living flora, where it is retained at all, it is usually in the form of stipules, which have all conceivable shapes and differ in all degrees in their permanence, some being appropriated to other uses according to the law of vicarious function. Others are persistent as small organs of different forms. Still others are deciduous at varying stages in the growth of the leaf, some, as Mr. Tyler shows, never being seen except on dissecting the bud. The last stage in this process is their complete atrophy and the resultant wholly exstipulate leaf.

The third lesson that we learn from Mr. Tyler's studies is that monocotyledonous plants constitute an early stage in the process of leaf development. This is what would have been naturally supposed, but there has been a tendency of late to cast doubts upon the position of the monocotyledons and to maintain that they are as highly developed and that they have been as late in their appearance in geologic time as the dicotyledonous angiosperms. It must be admitted that the paleobotanists have been the ones who have chiefly taken this view. This has been due to the exceedingly meager representation which the monocotyledons have in the fossil floras of the globe, and especially to the natural doubts which have arisen as to the botanical character of most of the fossil forms that have been regarded as monocotyledons by certain authors. The Yuccites of Schimper, from the Lower Trias, as also his genus *Ætho-phyllum*, which he did not himself refer to that class, but which others have naturally regarded as a monocotyledonous plant, cannot certainly be claimed as ancestral monocotyledons, although the proof to the contrary is equally wanting. Scarcely anything that has been discovered in the great Jurassic floras of the world has even been called monocotyledonous, and very little that is certainly such occurs even in the Cretaceous. It is, therefore, been held by some that this class of plants first made its appearance with the palms of the Eocene, but so rich and varied is this Eocene palm flora that it presents a case analogous to that which until recently was offered by the dicotyledonous floras of the Middle Cretaceous, and requires the violent assumption that a great group of plants suddenly burst in upon the world and attained all at once a high state of development in widely separated regions. This assumption is now thoroughly disproved in regard to the dicotyledons by the discovery of early embryonic types at a much earlier age, naturally leading up to the higher types referred to.

The monocotyledons, from their very nature, are the least adapted of all forms of vegetable

life to be preserved in the fossil state, representing, as Saporta and Marion show, and as Mr. Tyler's researches fully bear out, the primitive form of leaf development, which consists simply in setting apart a portion of the growing plant to serve the purposes of leaves, consisting of more or less broad and elongated blades, usually embracing the stem and tapering gradually to a point, with the leaf bundles continued in straight lines parallel to each other throughout their entire length. They are, therefore, broadest at the base and least adapted to securing the ultimate purpose of leaves already mentioned, viz., the maximum amount of light and air. The process of leaf development began with this condition, and many of the forms in which the cotyledon is still single have acquired a blade, as, for example, many species of *Potamogeton*, *Smilax*, *Dioscorea*, etc. In *Smilax* and some other genera true stipules have been developed, along with the tendency towards their differentiation into tendrils and other useful organs.

An important obstacle to the preservation of monocotyledonous leaves in the fossil state is the absence in them of any definite joint or natural point of separation of the leaf from the stem, which is one of the earliest results in the process of leaf evolution, also involving the principle of the renewal of leaves at annual or other fixed periods, which has practically resulted in the indefinite multiplication of the leaves produced, increasing the chances of their preservation by the whole number of such renewals. The only chance for an ordinary monocotyledonous plant to become entombed and preserved in the fossil state is that the locality in which it grows shall become somewhat rapidly covered up, burying the entire plant so quickly that it cannot decay during the process. This, as anyone can see, must be an exceedingly rare occurrence. Still, there is no doubt that a large amount of monocotyledonous vegetation growing in bogs and marshes in estuarine regions that are slowly subsiding under the weight of materials brought down the streams, and which also aid in covering them up, has been, in fact, preserved in a very imperfect way, and many vague and puzzling objects occur in all collections made from such localities. They are found throughout the Mesozoic, in the form of short culm-like segments and imperfect bits of leaves so badly macerated that they are neglected by those who determine such collections. It is rarely possible to say what form of plant they really represent, and yet it is often clear that these remains belong to certain glumaceous forms, grasses, sedges, rushes, etc. Saporta, in his work on the Mesozoic of Portugal, described and figured, under the name of Poacites, quite a number of these forms from the Neo-Jurassic to the Albian, or through the Upper Jurassic and entire Lower Cretaceous. Others have been called Cyperites, Zosterites, Bambusium, etc. Numerous small seeds are also constantly occurring, which are for the most part unnamed or given such names as do not indicate their botanical affinities. Many of these probably belong to monocotyledonous plants.

Mr. Tyler's paper, with all its excellencies, conveys the impression of an unfinished production. One would say that in his hurry to use it as a thesis he had been obliged to close it up abruptly. Its most serious defect is the want of careful descriptions of the plates and figures explained in their numerical order for the convenient use of the reader. This condition of the paper suggests the probability that the writer has much additional material, and inspires the hope that he may have entered upon a much more extended and exhaustive series of observations along these suggestive lines.

LESTER F. WARD.

On the Genera of Rodents: An Attempt to bring up to Date the current Arrangement of the Order. By OLDFIELD THOMAS, F.Z.S. Proc. Zool. Soc., London, 1896, pp. 1012–1028. Issued April, 1897.

The order Rodentia offers peculiar difficulties to the student, both on account of the number of its species and the great variety of forms which it includes. The satisfactory arrangement of the thousand or more species now known is no easy matter, as shown by the attempts of several authors, notably Waterhouse in 1839–48, Gervais in 1848–53, Brandt in 1855, Lilljeborg in 1866, Gill in 1872, and Alston in 1876. During the last ten years more progress has been made in the study of mammals than

in any previous quarter of a century. New methods of collecting, and more thorough exploration of regions previously little known, have brought to light a host of new forms and furnished material for studies which have thrown new light on the relationship of many groups. More careful examination of the literature has likewise necessitated many changes in nomenclature. Thus it is not surprising that Alston's classification, which has been generally adopted during the last 20 years, should have become somewhat antiquated.

In many respects Mr. Thomas is peculiarly fitted for the task of 'bringing the arrangement of the order up to date.' As curator of mammals in the British Museum he has constant access to a collection of rodents, which includes representatives of all but 15 of the existing genera and is unrivalled in the possession of a large number of types. Perhaps no other zoologist is personally familiar with more species or has a better general knowledge of the Rodentia than Mr. Thomas. He has also done much towards placing the nomenclature on a sound basis and has kept fully abreast of recent morphological work.

Although his paper comprises only 16 pages, it is an unusually important contribution to the literature of mammals and its value is not to be measured merely by its length. Unlike Alston's paper, it contains no diagnoses, and is therefore merely a list of genera arranged by families and subfamilies. It is intended mainly as a convenient reference list for museum curators and writers who have neither the time nor the inclination to work out the relationships of genera. Its object is threefold, since it gives: (1) the position and sequence of the genera in their respective subfamilies; (2) the earliest available name for each genus, and (3) a reference to the original description. The results of the investigation here presented necessitated not only a study of the genera and families, but the selection of the proper name from a host of synonyms for each of the 160 groups which are considered worthy of generic rank.

It would have been very desirable if the list had included extinct as well as living forms and had been extended to subgenera, thus forming a complete conspectus of the order. In limiting it to living mammals the author restricted himself to forms with which he is personally familiar, and by omitting subgenera avoided a vast amount of work which would have inevitably delayed the appearance of the list.

The changes which have been made in the classification of Rodents during the last 25 years can be most clearly brought out by comparing the lists of Gill, Alston and Thomas, but in so doing it should be remembered that Thomas follows Alston as closely as possible in the arrangement of the higher groups. Gill in 1872 recognized 9 superfamilies, 20 families, 16 subfamilies, but mentioned no genera; Alston in 1876 gave 3 superfamilies, 18 families, 23 subfamilies and 100 genera; Thomas now admits 5 superfamilies, 21 families, 27 subfamilies and 161 genera.* The increase in the present list is due to elevating the Bathyergidæ, Heteromyidæ, Erethizontidæ and Pedetidæ to the rank of families, and reducing the Lophiomyidæ to a subfamily of Muridæ. About one half the additional genera are 'new discoveries' and the remainder are due to the breaking-up of old genera.

Recent writers divide the Rodentia into two suborders: Simplicidentata and Duplicidentata; and most of them have followed Alston's tripartite division of the Simplicidentata into Sciuromorpha, Myomorpha and Hystricomorpha. This simple arrangement has not proved satisfactory, since some of the outlying genera will not fit into either group. To meet this difficulty Thomas has added two groups: Anomaluri and Aplodontiæ, making 5 subdivisions of superfamily value, thus to some extent following Gill. But in the attempt to retain Alston's higher groups with the termination *morpha* and at the same time to distinguish others of lower rank he has introduced two subdivisions between family and suborder. The names adopted are unfortunate, since the terminations are not distinctive, having been used by different authors for divisions varying in rank from superfamilies to subgenera. It would be simpler to

*Only 159 are mentioned, but *Fiber* is inadvertently omitted, and *Chilomys* has been proposed since this paper was printed. Beside these *Sigmodontomys* and *Zygodontomys* have recently been described by Dr. J. A. Allen.

adopt Gill's termination *oidea* for all these groups, although such a course would reduce the Sciuromorpha to the same rank as the Anomaluridæ. The relation of Thomas' superfamilies to those of Gill and Alston is as follows:

Anomaluri=Alston's Anomaluridæ=Gill's Anomaluroidea.

Sciuromorpha=Alston's Sciuromorphia (minus the Anomaluridæ and Aplodontiæ=Gill's Sciuroidea+Castoroidea.

Aplodontiæ=Alston's Haplodontidæ = Gill's Haploodontoidea.

Myomorpha=Alston's Myomorpha=Gill's Lophiomyoidea + Myoidea + Myoxoidea+Saccomyoidea.

Hystricomorpha=Alston's Hystricomorpha =Gill's Hystricoidea.

Two of Thomas' subfamily names, Loncherinæ and Sigmodontinæ are open to question on grounds of priority. The Loncherinæ were separated as a distinct group by Burmeister in 1854, but Gray had previously recognized the subfamily Echimyna in 1825, and Gill adopted the name in the form Echimyinæ in 1872. *Echimys* and *Loncheres* both belong to the same subfamily, and Echimyinæ besides being more generally used than Loncherinæ has several years' priority. Sigmodontinæ must give way to the well-known term Cricetinæ, the change having been made through a misapprehension as to the validity of the generic name *Cricetus*. As will be shown further on, there is no reason for rejecting *Cricetus* or the subfamily of which it is the type.

The instability of generic names is strikingly exemplified by this list. No less than one-eighth of the genera have been 'changed' during recent years, and in the attempt to find names which have unquestioned priority and are not preoccupied, the author has introduced unfamiliar terms for about 10 per cent. of the genera. In all such cases, however, the commonly accepted designations are added in brackets. But it may be questioned whether he has really carried this work far enough, for several of the names left undisturbed are open to objection.

Arctomys, which is usually credited to Schreber, 1792, can be traced back to 1780, but even with this early date it will probably have to give way to *Marmota* Blumenbach, 1779. The latter appeared in the first edition of the Handbuch d. Naturgeschichte—a rare volume, which is not accessible at present, and hence it is impossible to ascertain what species were originally placed in the genus.*

Hamster Lacépède appeared in 1801, whereas *Cricetus* was described by Cuvier in 1798, although not named until 1800. It was, however, defined by Kerr in 1792, and therefore antedates *Hamster* by not less than nine years. This is an excellent illustration of the importance of ascertaining the first publication of a name. Quoting *Cricetus* from Cuvier, Thomas assumes it to date from 1817 and rejects it in favor of *Hamster*, 1801. Had he found Cuvier's first use of the *Cricetus* in 1800 he would have avoided changing a name which must now be restored.

Cœlogenus Cuvier, 1807, appeared six years later than Lacépède's *Agouti*, the latter having been published in the Mem. de l'Institut, Paris, III., p. 494, 1801. As both of these genera were based on the same animal, *Agouti paca* (Linn.) is the proper name for the common paca.

Lagostomus Brookes, 1829, is antedated by *Vizcacia* Schinz, 1824,† and should be replaced by it.

Ellobius Fischer, 1814, may be considered untenable by some zoologists because of the prior use of *Ellobium* by Bolten in 1798 for a genus of mollusks,‡ but those who reject *Ellobius* must find a substitute for it, probably in *Chthonoergus* Nordmann, 1839.

The references to the original description of each genus in the list will be found very useful, but in a number of cases the names were actually published from one to twelve years

*In the 7th edition of the same work, published in 1803, Blumenbach included *Marmota alpina*, *M. cricetus*. *M. lemmus*, *M. typhlus* and *M. capensis*.

†See SCIENCE, New Ser., VI., July 2, 1897, pp. 21–22.

‡Museum Boltenianum, 1798. See Adams, Gen. Recent Moll., II., 1858, p. 237. Both names are derived from the same Greek word, the neuter noun ἐλλόβιον, an ear ring. Should it be desirable to place the mammal genus in a separate subfamily, as Gill has already done, the designation Ellobiinæ becomes identical with that in use for a subfamily of mollusks.

earlier than here indicated. The author could hardly be expected to verify all his references and had he done so the result might not have justified the labor. Nevertheless, the failure to find the original description may result in an error which will necessitate a change in the type of a group or may even lead to the rejection of a valid current name as in the case of *Cricetus*. As Mr. Thomas has evidently given merely the references usually quoted by authors, the remarks on this part of the paper should be regarded as supplementary notes rather than criticisms. For the benefit of those who may use the list, the earliest references are given below for genera which were published before the dates assigned by Thomas:*

9. *Arctomys* Schreber, Säugthiere, plates CCVII.–CCIX.,1780, text IV., pp. 721–743, 1782 (not '1792').

16. [*Myoxus* Schreber, Säugthiere, IV., plates CCXXV. A–B, CCXXVII., 1782, text IV., pp. 824–831, 1787] (not '1792').

19. *Graphiurus* F. Cuvier, Proc. Zool. Soc. London, p. 5, July, 1838 (not '1845').

31. *Rhombomys* Wagner, Gelehrte Anzeige K. Bay. Akad. Wiss. München, XII., pp. 421, 429, 433, March, 1841 (not '1843').

35. *Dendromus* A. Smith, Zool. Journ., IV., pp. 438–439, Jan.–May, 1829 (not '1834').

61. *Cricetus* Kerr, Anim. Kingd., I, Mamm., pp. 42, 242–246, 1792 (not Cuvier, '1817').

72. *Rhipidomys* (Wagner), Tschudi in Wiegm. Archiv. 1844, I., p. 252 (not '1845').

96. [*Cuniculus* Wagler, Nat. Syst. Amphibien, p. 21, 1830] (not '1832').

— *Fiber* G. Cuvier (Tableau Elem. d'Hist. Nat. Anim., p. 141, 1798), Lecons d'Anat. Comp., I., Tabl. 1, 1800.

100. *Tachyoryctes* Rüppell, Neue Wirbelthiere z. Fauna von Abyssinien, Säugth., pp. 35–37, Taf. 12, 1835.

108. *Heteromys* Desmarest, Nouv. Dict. d' Hist. Nat., 2d ed., XIV., pp. 180–181, 1817 (not '1822').

115. *Dipus* Schreber, Säugthiere, pls. CCXXVIII.–CCXXXII., 1782, text IV., pp. 842–861, 1788–89 (not 'Gmelin, 1788').†

137. *Echimys* Cuvier, Nouv. Bull. Soc. Philom., p. 394, Sept., 1809 (not '*Echinomys* Desmarest, 1817').

155. *Dolichotis* Desmarest, Journ. de Phys., LXXXVIII., p. 211, March, 1819 (not '1822').

But however desirable it may be to obtain the earliest reference, a generic name can not date farther back than 1758 (the year when the 10th edition of Linnæus' Systema Naturæ was published) or before the time when it was used as a scientific and not a vernacular name. Brisson's genera of 1756 must date from 1762, and French names should not take precedence over others published later, but before the former appeared as Latin names. The following genera should therefore be quoted as indicated below:

Spermophilus Cuvier, Dents des Mamm., 1825, pp. 160–161, 255, pl. LV. (not 1822), *Glis* Brisson, Regn. Animale, ed. 2, 1762, pp. 13, 113–118 (not 1756); *Atherurus* F. Cuvier, Dict. Sci. Nat., LIX., 1829, p. 483 (not G. Cuvier, Règne Animal, 1829); *Cercolabes*, Brandt, 1835, Mem. Acad. Imp. Sci. St. Petersburg, 3d ser., III., pp. 55–58 (not F. Cuvier, 1822); *Hydrochœrus* Brisson, Reg. Animale, 1762, pp. 12, 80–81 (not 1756).

Neither should the *apparent* date of publication be accepted when there is evidence to show that the name actually appeared earlier or later than indicated by the title page of the volume in which it was printed. For this reason *Anomalurus* should date from January, 1843, not 1842; *Psammomys* 1828, not 1826; *Oreinomys* 1881, not 1880; *Saccostomus* 1846, not 1847; *Acomys* 1838, not 1840; *Chiropodomys* 1868, not 1869; *Zapus* 1875, not 1873; *Pectinator* 1856, not 1855; *Schizodon* March, 1842, not 1841; *Chætomys* 1843, not 1848; *Lagostomus* 1829, not 1828. This question of exact dates may seem a very trivial matter, but when a difference of only a year or two in publication has necessitated the rejection of such well known names as *Arvicola*, *Isomys* and *Ochetodon*, it can readily be seen that, unless the date of publication is fixed with precision, generic names will never be stable.

*To these may be added *Fiber*, omitted from the list, and *Tachyoryctes*, which has no reference.

† Those who agree with Sherborn in not recognizing names on plates must quote *Dipus* from Boddaert's Elenchus Animalium, 1785, p. 47. In either case the authority is not Gmelin, as given by Thomas.

In two minor points the list is fairly open to criticism, namely, in the abbreviation of authorities and references, and in the emendation of names. Even those familiar with the literature will find difficulty in recognizing Ogilby in 'Og.,' Brants in 'Bts.,' Hemprich and Ehrenberg in 'H. & E.,' or in telling whether 'Sm.' stands for Smith or Smuts. In most cases Mr. Thomas has followed the original spelling of a name, but apparently with some hesitation, for he finds it necessary to apologize for *Aplodontia*, stating that he looks 'with loathing on these h-less names.' He has, however, adopted the emended forms *Echinomys* for *Echimys*, *Cannabateomys* for *Kannabateomys*, *Pithecochirus* for *Pithecheir*, and *Acodon* for *Akodon*, although in a paper subsequently published he has reverted to the original spelling, *Akodon*.

There is opportunity for much divergence of opinion as to the sequence and relative rank of the groups, for example, as to the wisdom of reducing the Lophiomyidæ to a subfamily of the Muridæ, while giving *Pedetes* and the American Porcupines full family rank. Some may question the removal of the Batherginæ from the Spalacidæ to form a separate family placed after the Geomyidæ and Heteromyidæ, so that the Old World genera *Spalax* and *Bathyergus*, which were formerly arranged side by side, are now separated by two families of New World pouched gophers and pocket mice: Possibly, it may seem that the author has recognized a relatively large number of genera of Muridæ, in view of the statement that all the recently proposed genera of Geomyidæ "may be most conveniently treated as of subgeneric rather than generic rank, sound as their basis as natural groups no doubt is."

But whatever difference there may be in regard to minor points, the fact remains that this paper admirably fulfills its purpose as a check list of genera of Rodents. We may venture to hope that the field having now been cleared to a certain extent of nomenclatural difficulties, Mr. Thomas will soon undertake the work which has so long been needed, namely, a complete catalogue of the Rodentia.

T. S. PALMER.

WASHINGTON, D. C.

SOCIETIES AND ACADEMIES.

NEW YORK ACADEMY OF SCIENCES—BIOLOGICAL SECTION, APRIL 5.

PROFESSOR OSBORN moved that a committee be appointed to consider and take action on the question of postage on natural history specimens. The chair appointed Doctors Dyar and Dean and Professor Stratford. Professor Bristol offered his resignation as Secretary. It was accepted, and the election of his successor was laid over until the next meeting.

Professor Osborn reported upon the phylogeny of the early Eocene Titanotheres, showing that they are divided into two distinct series, included under the genera *Telmatotherium* and *Palæosyops*, both of which independently acquired horns. The Telmatothere line begins with *T. boreale*, a form which Cope referred to as Palæosyops. It is distinguished by animals with long narrow skulls and high stilted feet, and undoubtedly represented the upland types of the family. The Palæosyops line, as suggested by Earle and Hatcher, passes through *P. laticeps* and *P. manteoceras*, and leads up to Diplacodon, the larger species of which surpass in size the smaller Titanotheres of the Oligocene. The main line gives off several collaterals, such as *P. paludosus*. Lambdotherium does not belong in the Titanothere phylum at all.

A second note related to a division of the two groups of placental mammals, the Meseutheria and Ceneutheria. The former, since Wortman's demonstration that the Ganodonta are ancestral Edentates, must now embrace this division, besides the Creodonta, Lemuroidea, Tillodontia, Insectivora, Amblypoda and Condylarthra.

The third note related to the origin of the typical mammalian types of teeth among the Theriodonta, Cynodontia and Gomphodontia of the Triassic. It is especially noteworthy that the Gomphodontia afford a demonstration of the origin of multituberculate teeth from a tritubercculate ground plan, as hypothetically assumed by the speaker some years ago.

Mr. Bradney B. Griffin reported that in Thalassema (one of the Echiurids) the spireme occurs in minute ova (3 micra in diameter) floating in clusters in the body cavity. The spireme segments into one-half the somatic

number of chromosomes, which by partial longitudinal splitting pass into flattened ellipses. These elongate, and during the growth period become twisted and distorted, and their true shape is thereby obscured. While entering the first polar spindle they appear as loose open rings or compact rods (bivalent). These by concentration and looping up form crosses, opposite arms of which are attached to the 'Zugfasern.' During metaphase the crosses become drawn ont into flattened ellipses which split across into two V's with closely apposed limbs. At telophase the latter separate at the angle and diverge in the second polar mitosis. No longitudinal splitting of the V's occurs.

In Zirphæa (Lamellibranch) the process is identical, although more obvious by reason of the less close apposition of the halves of the rings and V's. The conclusion is that in both forms a reducing division takes place.

Mr. J. H. McGregor offered a preliminary report on the development of the Spermatozoa in Amphiuma. Professor F. E. Lloyd's paper on Pholadidæa of the Pacific Coast was read by title.

C. L. BRISTOL,
Secretary.

MAY 3, 1897.

Mr. Gary N. Calkins, of Columbia University, was elected Secretary of the Section.

In the absence of Dr. Dyar, chairman of the committee appointed to consider the question of postage on natural history specimens, Professor Stratford reported that the Postmaster-General had been notified, and that the matter had received due consideration.

Upon behalf of the committee appointed to draw up a resolution relating to the death of Professor Cope, Professor Osborn delivered a brief eulogy of the great naturalist, pointing out the especial features which have made his work famous and have given him such a high position in the history of natural science. He dwelt especially upon the fact that Professor Cope prosecuted five great lines of work simultaneously, and that in each he acquired a commanding position. He also spoke of some of his generous qualities as a fellow scientific worker, especially his liberality in the loan of collections and generous recognition of the work of others. Finally, he alluded to his remarkable independence and fortitude of character, and persistent devotion to science, even with limited resources. His death leaves a vacuum especially in the line of able and accurate criticism of contemporary work. Professor Osborn concluded by submitting the following resolution:

The members of the New York Academy of Sciences desire to record their admiration of the noble services to science of the late Professor Edward D. Cope. Since 1895, when he offered his first contribution to the Philadelphia Academy of Sciences, at the age of nineteen, he has been a devoted and brilliant investigator in five great branches of natural history—ichthyology, herpetology of the batrachians and reptiles, mammalian paleontology, historical geology and philosophy. In each he has long been an acknowledged leader, and his combined knowledge of all has given his researches a philosophical breadth, grasp and permanence which place him among the great masters of comparative anatomy—Cuvier, Owen and Huxley. We deeply regret that his untimely death has cut short his life work, and feel that the loss of his keen, critical and productive faculty deals a blow to the cause of comparative anatomy of the vertebrata throughout the world, which can hardly be measured. We tender to the American Philosophical Society and to the Academy of Natural Sciences of Philadelphia, of which Professor Cope was a life-long member, an expression of our deep regret at their loss, and of our readiness to cooperate with them in the establishment of some suitable memorial.

Signed: HENRY F. OSBORN.
J. L. WORTMAN.

Mr. H. E. Crampton, Jr., gave a brief abstract of a paper by F. C. Baker on 'Notes on Variations in the apex of Gasteropod Molluscs.' Professor Bashford Dean and Mr. F. P. Sumner reported on the spawning habits of *Petromyzon Wilderi* at Van Cortlandt Pond. Mr. H. E. Crampton, Jr., reported on some Coalescence Experiments with Lepidoptera. A paper on the 'Vertical Distribution of Plankton in Deep-Sea Collections from Puget Sound,' by Professor James I. Peck and N. R. Harrington, was read by title.

G. N. CALKINS,
Secretary.

*PHYSICAL ANTHROPOLOGY.**

PHYSICAL anthropology is that branch of the broader field of anthropology which treats of physical man. It has nothing to do with man as a social being; it is not concerned with the products of his hands or of his brain; it deals neither with technology, language, government, law, sociology, folk-lore nor religion; it treats of man as an animal.

We may for the sake of convenience consider four views of the subject. These are: (a) the scope of physical anthropology; (b) the problems of physical anthropology; (c) physical anthropology in its relation to museum exhibition; and (d) the importance or value of physical anthropology.

(a) *The Scope of Physical Anthropology.*

Physical anthropology assumes that man is an animal; is a member of the brute world, and it follows that man is to be studied as other animals are studied. It is then a part of zoology, which has for its study the entire animal world; and in this world man demands the most attention and the closet scrutiny, for he is both the most important and the most widely distributed of all animals. Applying the methods of zoological investigation to man, physical anthropology asks of his ancestry, of the time of his appearance on earth, of his kinds or varieties or species, of the comparative fertility of races, of the fertility of hybrids, of the laws of heredity and descent, and of the nature and influence of food, climate and environment upon man, and finally of man's relation to other animals.

* A lecture delivered at the Field Columbian Museum, March 20, 1897.

It becomes evident at once that in the various investigations which are instituted in the study of physical man we must have the assistance of other studies which are closely related. Thus by the aid of paleontology we may hope for light on the problem of man's first appearance, both in time and place, and also on the problem of man's ancestors, for paleontology is simply the study of zoology in geological times; it is the archaeology of zoology. Again, by the aid of embryology, we may hope to learn something of man's origin, for it is one of the laws of biology that the developmental history of the individual is an epitome of the developmental history of the race. With the aid of anatomy, the study of gross structure, we are able to compare the varieties of men and so classification and division become possible, and by means of comparative anatomy we can compare man's structure with that of other animals and thus learn of relationships. With the aid of physiology and experimental psychology we are enabled to judge of the comparative physical functions and mental activities of the different races. It must be added that no one or even all of these studies combined is physical anthropology. The data which they severally and collectively furnish make possible the broader, more comprehensive study of physical man.

It is well also that we remind ourselves that the study of physical anthropology has only recently become a possibility. The time was not so very long ago when man rebelled at the thought that he had anything in common with the animals; he forgot or overlooked the fact that his entry into and exit from this world were like other animals, that his life was and is a struggle for existence, that his physical nature was so like that of animals that the same laws of evolution which produced the one must have produced the other, must have produced all, must govern all. And so the skeptics of the scientific and unscientific world cried: Produce your missing link! The 'missing link' is dead, and almost forgotten, but in his stead has arisen, from the study of paleontology, embryology and comparative anatomy, an array of facts which unite man to the animal world in a manner so close and intimate as to admit of no questioning. As one anatomist* says: "Blood relationship and not some unknown plan of creation forms the invisible bond which unites organisms in various degrees of similarity, and in this great family man must find his place. He forms but a link in the chain, and has no right to consider himself an exception."

It may seem strange that after physical anthropology has been declared to be that part of zoology which deals with man that there should be any need to speak of the *methods* which are essential to its proper study. But the field offers such large opportunities for superficial work, and so much of that sort has been done that we may well devote a few minutes to the consideration of this subject. We hear so much of 'reversions,' 'simian traits' and 'anthropoid characters' that we are bewildered, and after all the evidence is in we can only conclude that man's ancestors were wonderfully and fearfully made. There is, indeed, in the different races of men, or in any one of them, an enormous amount of variation. A naturalist† asks: "Are not Esquimaux and Bushmen, Samoyedes and Australians, American Indians and Fantis much further apart than any two species of monkeys, of larks or butterflies?" While an anatomist,‡ speaking of the shoulder-blade, says: "I do not know what range of

* Wiedersheim: Structure of Man, p. 2.

† Sir Henry Haworth: *Natural Science*, Sept., 1896, p. 185.

‡ Professor T. Dwight: The Range and Significance of Variation in the Human Skeleton. Boston, 1894, p. 23.

variation a great series of the scapulæ of the larger felidæ might present, but a small one shows nothing like that of the human race, and I might even add that of the Caucasian."

But because certain parts of man's skeleton bear close resemblance to the gorilla, other parts to the chimpanzee, still others to the orang and gibbon, does it follow that man, in his race history, has been successively a gibbon, an orang, a chimpanzee and a gorilla? Surely it would seem no one would claim for man such a pedigree as this, but this has been done, if not openly, it at least has been tacitly implied. And hence the need of definite scientific methods which make such reasoning impossible. Naturally, all the methods of zoological investigation are not applicable in the study of the human species, but at least two are of the utmost value; they are the statistical, or mathematical, and the morphological. The use of the statistical method in anthropology, and its extension in zoology, is due very largely to Mr. Francis Galton. Its basis is an application of the laws of chance, and Galton has devised special apparatus to illustrate its application. The method is of great value in comparative studies, such, for example, as the various indices, which are determined from measurements on the skull. Thus, if we take the length of the skull in a thousand individuals, and arrange the results according to their distribution, we shall have a curve, the character of which will be determined by the uniformity of the individuals measured. If they are all of one race, and that race is free from admixture with other races, we shall expect to find a curve which is high in the center and of a uniform character. If, on the other hand, the race is a mixed one the curve will be broad in proportion to its height and will be irregular in its course. In other words, the character of the curve is largely determined by the number of disturbing causes. Just as in Galton's apparatus, the character of the curve described by shot which falls upon a compartment, striking in its passage pins, will be determined by the height from which it falls and the number of pins it encounters in its passage. By means of these curves, that is, by the use of the statistical method, the greater part of anthropometric investigations are shown.

In the second method, the morphological, we deal with form and arrangement, and the unit is not the individual, but the species. The method proceeds by homology and it recognizes in variation an indication of the slow modification of the race or species. In other words, morphology is simply an extension of comparative anatomy. It calls to its aid embryology and histology, or the study of minute structure. A character which appears occasionally in man and is always present in the apes is not to be called 'simian' until its pedigree has been carefully determined and it can be shown to have been a transmitted character or an actual reversion. A close adherence to the methods of morphology may not unravel all the problems which are presented in man's strucure, but it will make impossible many of the so-called deductions which thus far have been put forth in the name of physical anthropology.

(b) *Problems of Physical Anthropology.*

We have to consider in this place not so much what has been done as what remains to be done, for, although much has been accomplished, the field of investigation still remains very broad. In the first place, we do not yet know the exact lines of man's descent. His cousins are pretty well known, but his immediate ancestors are not yet discovered. There is yet to be learned even the approximate time of man's appearance *as man* upon earth. That time has been stated within the last year by one writer to

have been 15,000 years ago, by another to have been 200,000 years ago. The extreme antiquity of man's appearance is no longer questioned, for in Europe his remains have been found associated with the bones of long extinct mammals. Further evidence of his great antiquity has been found in Africa, Asia and America, and only recently remains have been found in Java which have up to this time defied the best anatomists of Europe to determine whether they belong to man or to some extinct ape. At any rate, they may be characterized as the most human-like of the apes so far known, or the most ape-like of any man yet discovered. But the real importance of the find in Java lies in the fact that we may hope for further discoveries which may throw light on man's origin. There are still vast areas of Quaternary and Tertiary deposits in Asia, Africa and the islands of the Indian Ocean which await investigation, and it is not too much to hope that the next twenty-five years will see greater advances in our knowledge of man's past history than we have seen in the last century.

There is another problem awaiting solution and it is, to a certain extent, bound up with the one just considered; it is the old question, put in a new form, of the single or multiple origin of man—monogenism or polygenism. The facts as at present known are these: With the exception of the Java find and possibly one or two skulls found in Europe, man seems to be not only *man*, but go back as far into the past as we can, we find the several types of mankind already existing as we know them to-day. On the most ancient of the Egyptian monuments we see depicted in a distinct manner the Egyptian Fellah, the Hadandowah and the Negro. If we consider the skulls which have been found in Europe and America along with bones of extinct mammals we have the long heads and the short heads—the types which appear to-day, and which furnish much of the basis of anthropological classification. Where or when did the lines begin to diverge? Was it due to a plurality in man's ancestry or was it due to environment? And why have the types of ancient times persisted down to the present day? We do not know yet why the skin of the negro is black, any more than we know why it remains black; nor do we know why his hair in cross section is long and narrow in shape, while that of the Indian is circular.

These questions and riddles are simply part and parcel of the great problem of heredity, and if the study of anthropology does no more than solve that, it will amply have earned its title to recognition. A distinguished English anthropologist declares that even to-day there may occasionally be noted the reappearance of physical types which existed in Europe contemporaneously with the cave-bear and the mammoth; while one of America's foremost anatomists has declared that in the occasional appearance of a third trochanter we have a survival of a structure which is an essential feature of the horse and the rhinoceres. When we know preciesly what heredity means, what can be inherited and what can not, then we may hope to know more of man's origin and of his destiny.

But the subjects of investigation are not only to enquire into the past; they include the men, the races of to-day. Surely the field is broad enough here, and no one who has explored even a corner of it doubts its importance and interest. But how much do we know of it? The physical history of the races of Europe has only been written within the last five years and it is far from complete. What do we know of the peoples of Africa or of the aborigines of America? Not nearly as much as we know of the mammals or of the butterflies of these countries. Yet in these peoples we have, if we would but look, a picture

full of suggestion as to man's primitive condition. It is as if the geologist could visit some remote spot and behold the earth as it existed in Tertiary times. Would he neglect the opportunity? In many of the peoples of Africa and Oceania we find types of bodily structure which are not described in the anatomical text-books of Gray or Quain. There we may see important differences from the European type in cranial capacity, in the size and structure of the brain, in the relative lengths of the arm and leg, in the pelvis, in the musculature of the hand and foot, in fact in the entire bodily structure; and these differences are significant. In the heart of Africa are dwarfs that in bodily structure and mental calibre are very far removed, indeed, from the European. In other parts of the world dwarf races have lately been discovered. Are they the survivals of primitive times, or are they the degenerate offspring of a once vigorous ancestry? These are a few of the subjects still awaiting investigation.

The field is surely broad, but how little cultivated! The proper study of mankind may be man, but curiously enough man does not seem to have cared to study mankind. As one of America's foremost students of anthropology has pointed out, man 'has never seriously and to the best of his abilities made a study of his own nature, its wants and its weakness, and how best he could amend the one and satisfy the other.' The reason for this is hard to discover, but for the present we are most concerned in the consequences; and to illustrate the extent to which a lack of the desire to study man will lead, we may take a single example. Among the general instructions to the officers of the Challenger Expedition we find the following:* "Every opportunity should be taken of obtaining photographs of native races to one scale; and of making such observations as are practicable with regard to their physical characteristics, language, habits, implements and antiquities. It would be advisable that specimens of hair of unmixed races should in all cases be obtained." And what was the result? From an expedition which in its importance ranks only after that of Columbus and Magellan; which consumed years of time and cost the British government in round figures $600,000—from this expedition the total contribution to the knowledge of the races of men were some notes by two of the officers, a few unsatisfactory photographs, a few bones of skeletons and *sixty-four* skulls! There is a serious side to such a neglect of opportunity as this.

*I am indebted for this information to *Natural Science*, Vol. VII., No. 41, Special 'Challenge' Number, pp. 7 and 74.

In 1803 Tasmania's population was 7,000; to-day there is not a single representative left. In 1842 the Maoris of New Zealand numbered 140,000; to-day there are less than 30,000. When Macaulay's New Zealander gazes on the ruins of London there will be no New Zealander; the name 'Maori' even will be as unfamiliar then as is now the name of some obscure Germanic tribe of the times of Tacitus. What is true of New Zealand is rapidly becoming true of all the islands of the Pacific; it is true of nearly all the North American continent and for large areas of the Southern.

The field for the study of physical man is broad, but the scene is ever changing, and it behooves us to-day, if we would not merit the just condemnation of the ages to come, to observe, to record, to make use of the camera, the phonograph, the calipers and the color-scale. But how often on any of the great scientific expeditions is there any one fitted by previous training to observe correctly and accurately the races of men that may be encountered? Recall, if you please, the numerous expeditions which have penetrated Africa, crossed Asia and

traversed the islands of the Pacific, and we find men competent to observe and collect reptiles and birds and fishes and mammals, to study botany and geology, but how often is anthropology represented? Surely no one doubts that previous training is just as essential in the one case as in the others. But there is already an attempt in some countries to remedy this. In London, Paris and Berlin one can receive instruction from competent teachers as to the best methods of recording and observing, as well as a knowledge of what is best to observe and record. As a result of this, a widespread interest is being manifested in anthropological matters by army and naval officers, as well as by the civilians of the European countries, and there is growing up in each of the great Continental cities storehouses of information about the peoples of the different parts of the world. Not only that, but the universities are awakening to the importance of the study of man. As a sign of the times, we may read in one of the February numbers of *Nature:* "Dr. A. C. Haddon is this term giving two well-attended classes (one elementary and one advanced) in physical anthropology at the Anatomy School." And what is true of Cambridge is true to a greater or less extent of fifteen other European universities.

In America, while general instruction in anthropology has for number of years been given in several universities, a special course in physical anthropology is offered by Dr. Boas in Columbia for the first time this year, and in the University of Chicago courses covering the entire field of physical anthropology have been given by Professor Starr since its foundation.

(c.) *Physical Anthropology in Relation to Museum Exhibition.*

Up to the present time there is no museum or section of museum which adequately or worthily represents the subject of physical anthropology. There are museums of zoology, of botany, of geology and of anatomy, but no museum which shows the races of men as they should or might be shown. Obviously, it will be beyond the limit of our time to treat, with any degree of fullness, of the possibilities of a museum of physical anthropology, but we can at least attempt to lay down the general lines on which a museum should be built, and which ought to be possible of accomplishment.

The ideal museum of physical anthropology then will have at least three sections or divisions. In the first should be shown the instruments and apparatus which are used for making and recording the various observations which are taken both on the living subject and on the cadaver or skeleton. By the use of charts and diagrams the methods of tabulating and recording these observations may be shown. There ought, furthermore, to be in this section a room or rooms in which an individual who applies can be measured or tested according to the accepted standards of anthropometry and psychometry. Such facilities would serve a twofold purpose. To the subject they tend to awaken an interest in himself and may be useful in indicating physical and psychical defects or weaknesses which may be easily remedied. From personal interest in the subject to a broader and more thorough understanding of the aims and methods of anthropology, is a matter of easier accomplishment after the individual has had even this slight introduction to the science. On the other hand, these observations on the living subject, when made in sufficient quantities, enable the observer to draw valuable deductions in regard to vital phenomena, such as the laws of growth, sexual differences, the influence of nationality, of climate, of nourishment and of occupation, together with the effect of all these on stature, on lung capacity, on strength, on mental activities, etc. Much

has been done along these lines that is valuable, but many important problems have yet to be investigated, the solution of which will help not a little to a more correct understanding of the possibilities and limitations of human life.

In the second section of this ideal museum the aim will be to interpret and explain physical man. Naturally, the subject is treated in the broadest and most general way, the object being primarily to exhibit man as a zoological unit; but there must be many sub-sections or divisions. In one group we may properly begin with the embryological history of man. Such an exhibit is not only possible, but, owing to the improved methods of museum display, can be made very attractive as well as instructive. Not only can man's interuterine life be shown by means of alcoholic specimens, but this may be thoroughly well illustrated, and even the early stages rendered visible, with the aid of the wax and plaster models, which are now made with the greatest exactness and scientific accuracy. With such assistance, many of the most interesting facts of man's history can be made clear. For example, as the various stages of embryonic life are unfolded, we see as it were an epitome of man's past history, for it is one of the laws of biology that the developmental history of the individual is a resumé of the developmental history of the race. By the illustration of this law, as man is seen to pass successfully from the stage of a single cell, through that of a jellyfish, when later he has the gill pouches of a fish, and the freely projecting tail of mammals, the fact is burned in that man is but a 'link in the chain.'

Another subsection will be devoted to the skeleton. No matter where the skeleton is to be placed or what part it is to play in the exhibit of other branches of zoology, in physical anthropology its place is *not* in the closet, but in full sight; and one museum at least in America has ably demonstrated that the skeleton can be made as beautiful, as attractive and as interesting as any subject of a natural history exhibit.* Furthermore, the skeleton may or may not be morphologically valuable;† it forms an extremely important part in any exhibit of man. Of all the bodily systems it is easiest preserved and the most enduring; it alone of the body furnishes us with our knowledge of extinct and fossil man.

The first object in the exhibit of the skeleton is to make easily familiar the names, positions and relative importance of the various members, individual bones and parts of bones; in other words, there should first be an illustrated text-book of normal human osteology. The visitor is then prepared for something better and we may next show the development of the skeleton. First to be shown would be the fœtal skeleton in ligamentous preparations, and then a series of articulated skeletons, ranging in age from birth to full maturity, terminating with the skeleton of old age. The attempt may next be made to show the range of variation of the skeleton, not for the European race, but for man, drawing for our material upon all races. This series can be made of the greatest interest, and when properly formed and labeled is of the utmost importance. We should have in this group two series, one showing the descriptive variations or those which can easily be detected by the eye and readily and fully described in the labels; the second series illustrates those variations which are best described by terms of mathematical precision. As an example of the first series we may mention, to take the skull alone, the variations in the sutures or lines of articulation of the bones, their degree of serration, the time in life of closure, the

* The Wistar Institute of Anatomy and Physiology in Philadelphia.

† Cf. Minot's Human Embryology, p. 422.

influence of the shape of the head by premature closure, anomalous sutures such as the persistent frontal or subsagittal or interparietal, and, finally, the supernumerary bones which appear occasionally in certain sutures. As examples of the second series we may illustrate such craniometrical observations as the variations in the cubic capacity of the skull, or the cephalic index—the relation of the length to the breadth of the skull; or, of other parts of the skeleton, the various forms of pelvic and scapular indices. Still another but minor group should illustrate the diverse forms of artificially deformed skulls which are found in various parts of the world, and along with them should be shown the cradle-boards, bandages and other appliances which were used to produce such deformation.

If we include the teeth in our exhibit of the skeleton there is much that can be shown. Thus we would have illustrated the time of eruption of the milk and permanent teeth, the degrees and causes of wear, the appearance of the jaws due to loss of teeth, and the changes which have taken and are taking place in man's dentition. Still another series or subsection presents in one comprehensive view the skeleton of man by the side of those of his first and second cousins, from the gorilla down to the lowest lemurs, including the models or casts of the earliest human bones which have yet been found. In fact, the limits are very wide to this section which is devoted to the skeleton. Many of the changes which have taken place in man's gradual acquisition of the upright position can be shown and made most instructive; such modifications can still be seen in the pelvis, the bones of the arms and legs, the shoulder-blade, and in the gradual shifting of the great body cavities, as seen in the variation in the number of ribs and vertebræ and the gradual shortening of the breast-bone. This, by no means, exhausts the interesting and instructive changes which can be rung on the skeleton and its component members. But all of this requires an unlimited supply of material from widely distinct races; it also requires, for purposes of illustration, free access to the skeletons of apes and other mammals, and even of lower vertebrates.

But of the first general section we have considered only one system of man's structure; the others should have their proper amount of attention. Here we meet with a real difficulty; the other systems are only prepared and exhibited at considerable labor and expense, and, worst of all, we can not have such free command of material from all races from which to draw. We can dig up the bony remains of the Papuan, but he refuses to be dissected. There is, however, much that can be shown. Take the muscular system; by means of alcoholic and dried preparations, and by following a definite scheme, we can hope to show some of the variations which demand 900 pages for their description at the hands of a French anatomist.* By a careful arrangement we can demonstrate that certain muscles are peculiar to man, those which are required by his upright position and especially by the extended use to which he puts his hands; that he retains other muscles which he no longer needs, as, for example, some of the muscles of his ears and feet; and, finally, that there are occasionally present muscles which, in general, man has lost, but which still survive in an extremely rudimentary condition in some men, such as the caudal or tail muscles.

With the *nervous system* the problem of exhibition becomes at once less difficult again, and the possibilities of museum display are very great. Those who were fortunate enough to have visited the Section

* Testut: Les anomalies musculaires chez l'homme. Paris, 1887.

of Neurology* in the Anthropological Building at the World's Fair need not be told of the pleasure which may be derived from a thoroughly well arranged exhibit of the nervous system. In the ideal museum it will be possible to read the story of the development of a man's brain, from its lowly beginning as an infolding of the outer germ layer to that complete organ of the adult which in its structural form so closely resembles the brain of the higher apes, but which in its potentialities and possibilities is as far removed as man himself is from the brute creation. But there is more than mere development to be shown. Even the brain of the adult is subject to great variation from the normal, and all these variations are interesting from the standpoint of morphology. Then there is the correlation of the brain to the skull which must be shown, along with the casts of the cavity of the skull. The subject is by no means exhausted yet, but enough has been said to point out, although imperfectly, the possibilities which this system lends to museum purposes.

Of the other four great systems of physical man I shall stop for only one, and in that shall select a single example. I refer to the variations in the arch of the aorta, the great blood vessel which leads from the heart. In all the systems or parts of systems of man's structure there is none, perhaps, which betrays his humble origin so well or so convincingly as the variations which we find here. It is not that in the embryological development of the circulatory system in general we can trace man's pedigree from a condition more primitive than that of the fishes, but that, to return to our example, in the adult variations of the aorta we may find a single aortic arch on the left side, the normal condition; or a single arch on the right side, the condition of birds; or a right and left, or double arch, the condition in reptiles.

* Under the able direction of Professor H. H. Donaldson, of the University of Chicago.

In all of these four great systems, to say nothing of man's outer covering, such as the skin and hair, there are similar interesting facts, which, by means of corrosive and injection preparations or preservative fluids, may be exhibited in an attractive manner and serve as illustrations for the text-book of humankind.

In the third section we do not consider man, but men; not the species man, but the varieties of men; and hence we may characterize this section as special or ethnic. The aim is to present, as compactly and attractively as possible, a bird's-eye view of all the groups of people from all parts of the world. Such an exhibit, properly made, carefully installed, and fully and accurately labelled, ought easily to excel in interest any exhibit that can be made of any department of science. An exhibit, for example, of a group of casts of Australians, true to life in color, expression, form and dress, is just as much more interesting than a group of stuffed kangaroos as a group of live Australians is of more interest than a group of live kangaroos; and for proof of the correctness of the latter observation one need only take a single glance at the distribution of a crowd at a circus.

As to details, of course, there will be much divergence of opinion, but we cannot go very far astray if we follow, as a general rule, a geographical order. There will be times, to be sure, when it will not be practicable or wise to do this, but if we begin with the dark-skinned races, such as the Negrittoes, Papuans, Australians, and Negroes of Africa, we can readily pass over to the brown or insular peoples of the Pacific, such as the Malays, Indonesians, etc. We can next take up the continent of America, and then, passing over into Asia by the northwest coast, can cross Asia and so finally traverse Europe. In this manner

we shall not only have circumnavigated the globe, but have done it in an orderly manner, and at the same time have kept near to the line of the physical development of the races.

Naturally, when we come to select the groups and tribes to be represented there will be more difference of opinion, but the main point is to select such groups as are *types*, those which show decided variation from their neighbors, either in color, in stature, in hair, or in physiognomy. The limit to be put on the number of the groups will, of course, be determined very largely by the means at our command for this purpose, but certainly an exhibit which includes less than sixty groups would be incomplete and more or less unworthy of the subject.

There is next to be determined the exact character or nature of the material which is to be included in each group. This again must, to a large extent, be a matter of expediency or possibility. For some groups an abundance of material will be available; for others we must be content with a scant amount. But still it will be possible to keep in mind a standard below which it will be unwise to fall. There should be on the one side the group of casts, colored and dressed with the utmost accuracy and scientific precision. From these figures can be studied the color, shape, size, hair, facial expression, relative length of limbs, shape of hands, feet, etc., as accurately as from the living subject. This should include at least three figures—the man, woman and child. By their side we may show the mounted skeletons, the scaffolding of the body. On the opposite side are series of skulls, shoulder-blades, pelves, long bones, etc., selected in such a manner as to present the typical osteological characters of the group we are representing. At the center and in the back are type photographs, anthropometric charts, diagrams of sections of hair, etc., and a map showing the exact geographical distribution of the group. Other maps or charts showing the physiography, fauna, flora and climate should be added whenever possible. Every object exhibited is to have its own individual label, and there is, of course, to be in the center a comprehensive label which sets forth in brief, concise language the chief characteristics of that particular group.

In other words, as the first section illustrates the aims, objects and methods of physical anthropology, as the second section defines and exhibits the species man and sets forth his position in the animal world, so this, the third section, is an illustrated text-book of races and peoples, of ethnography.

But we are not yet concluded with our scheme for an ideal museum, for so far provision has only been made for the casual visitor and the thoughtful student; provision must also be made for the investigator. A museum which fails to have its study series can never be considered complete. The museum can not, it does not, aim to supplant the universities, but it should aim to supplement them. It should clearly be borne in mind that the museum of to-day, if it is to be worthy the name, must be built up from the results of field exploration and investigation. No systematic or comprehensive scheme for a scientific museum can be carried out from random gifts and occasional purchases. Accessions from such sources as these may in time grow into vast *curio halls*, but never into the scientific museum worthy the building which houses it, or the time of its care-takers.

It is rare, indeed, that it is possible or desirable to place on permanent exhibition all the material which may be gathered from any single expedition. The duplicates, thus acquired, are too often regarded as encumbrances, fit only for purposes of exchange, or, if that be impossible, they are

piled away in the attic, or even, worse still, in the bottom compartments of the exhibition cases, there to grow mouldy or to be eaten up by the moths. But in the real museum such duplicate specimens, and those not suitable for exhibition purposes, are carefully assorted and those which may be of interest to the student or investigator are arranged in suitable compartments in well lighted rooms, where they may be readily available for study. Such series represent the 'stack' of a great Library; they make possible rearrangement and extension of the exhibition series, and, best of all, they give to the museum, in direct proportion to their fullness, completeness and permanency, and serve the purpose of awakening not a local, but a national interest. Such series would contribute largely to obviate the necessity of American students going abroad for material for study.

(d) *The Importance or Value of Physical Anthropology.*

And now, last of all, we have to consider this question: Is the study of anthropology worth the time, and is its proper exhibition worth the cost and labor? In other words, what is the ultimate aim of physical anthropology, what can it teach, what is its value?

The aim of physical anthropology is to *know* physical man, to unravel the mysteries of his nature. It follows the individual throughout the entire course of his life. It enquires into his origin and his evolution down to the present day. It enquires into the varieties of man and asks for the causes which have made these varieties; why are some men black, why are others white, and, more difficult to answer, it asks why the black remain black and the white remain white. Its aim is to enquire into the condition of physical progress, to study the effects on man of soil and climate; in short, of environment. It enquires into the laws of heredity and descent, into the laws of health and disease, and it asks for the factors which make for longevity and robustness, a sound mind in a sound body.

Physical anthropology teaches us that all men are not born equal; that every child at birth is "endowed with the heritage transmitted from innumerable ancestors, and is already rich in personal experiences from its prenatal life; that these combined decide the individual's race and strain, and potentially incline, if they do not absolutely coerce, his tastes and ambitions, his fears and hopes, his failure or success."* It teaches us that man has acquired, and only recently, his upright position, and that he is not yet perfectly adapted to it; that the evolution of sex has gone on further in man than in other mammals; that the entire structure is slowly and progressively modified from birth to adult age; that then retrogressive changes set in which, in some respects, are infantile in character. It teaches not only that there has been a gradual evolution of man's physical nature, but that influences are still at work which will produce yet further changes and modifications; that the man of the future will not be like the man of to-day.

The aim of physical anthropology is to know physical man, and herein lies its value; for when we know man then can we answer some of the problems which confront man, and on the proper solution of these problems rests the destiny of nations and the ultimate destiny of man himself. These problems are many, and demand immediate answer. Morphology, the study of variation, is the hand-maid of pathology, and a knowledge of the causes of disease will aid materially in its prevention. With a larger and more enlightened view of the effects of environment, we can hope to see

* Brinton: The Aims of Anthropology, SCIENCE, Vol. 11., 1895, p. 241; Proc. A. A. A. S., Vol. 44, p. 2.

solved the problem of acclimatization, a problem which so far has baffled physicians, and which has even been declared insoluble; but which, if ever solved, will change the complexion of the earth's surface and inaugurate a new era in the history of mankind. A broader knowledge of physical man will throw light on that most intricate and obscure problem of miscegenation or race-intermarriage, a problem which, it has been declared, is exceeded by no other in its effects on the 'future prosperity or failure of the human species.'

The study of physical anthropology teaches us that not only are all men not born equal, but that tribes and races and nations are inevitably doomed to give way and perish before the advance of their more fortunate fellow-men; that the time is not far distant when a certain few races will have peopled the globe, when no survivor of the native population will exist on a territory which covers an area of twenty-five million square miles and which, four hundred years ago, contained one hundred million inhabitants.

To know physical man, his past history, his present possibilities, his future destiny—such is the aim and value of physical anthropology, but not least in value is to teach him his place in nature.

GEORGE A. DORSEY.
FIELD COLUMBIAN MUSEUM.

THE ASSOCIATION OF AMERICAN ANATOMISTS.

THE ninth annual session of the Association was held in the Columbian University Scientific School, Washington, D. C., Tuesday to Thursday, May 4 to 6, 1897, in conjunction with the other societies comprising the Congress of American Physicians and Surgeons.

Dr. Frank Baker, President of the Association, presided at the several meetings. The following members were present at some time during the session: Baker, Bevan, Blake, Bosher, Browning, Carr, Dawbarn, Gerrish, Gill, Hamann, Hewson, Hodge, Hunt, Huntington, Hutchinson, Kemp, Lamb, Leidy, Mears, Miller, Mixter, Moran, Parkhill, Reisinger, Roberts, Shepherd, West and Wilder—28 in all.

The Association was called to order by the President who delivered an address, which will be printed in SCIENCE.

Dr. D. S. Lamb, Secretary and Treasurer, submitted his report for the period which had elapsed since the last session, December 27 and 28, 1895, which was accepted. The following are extracts: "No meeting was held in December, 1896, in view of the fact that this Association is a member of the Congress of American Physicians and Surgeons, which meets in this city in May every third year. The Executive Committee believes that if we should meet both in December and the following May the short interval between the meetings would imperil the success of the May meeting, at the same time regretting that by postponing the December meeting we lose the opportunity of attend- the sessions of the Society of American Naturalists and the affiliated societies. This is the second time this postponement has occurred and in the nature of things seems inevitable every third year.

"Since the last meeting three members have died. Sir George Murray Humphry, an honorary member, professor of surgery and late professor of anatomy in the University of Cambridge, England, died September 24, 1896. He is perhaps best known as the author of a classic work on 'The Skeleton.' Dr. Charles Heitzmann, of New York City, at one time lecturer on morbid anatomy in the University of Vienna, and who afterwards conducted a Histologic and Pathologic Laboratory in New York City, author of a work on anatomy, having occasion to go to Europe for his health, resigned September

16, 1896. Sometime afterwards I saw a notice of his death while abroad ; the exact date I cannot give. Professor Edward Drinker Cope, professor of vertebrate paleontology in the University of Pennsylvania, and author of many works on American Paleontology, died in Philadelphia, April 12, 1897."

The Executive Committee reported favorably on the following applications for membership: Drs. V. P. Blair, J. A. Blake, Thomas Flavin, C. M. Miller, J. T. Moore, and E. W. Reisinger and Mr. C. T. Ward; all of whom were elected.

Dr. Lamb, from the Committee on Anatomical Peculiarities of the Negro, reported a 'List of Items' and 'Letter of Instructions' to accompany the same. Dr. Wilder suggested several changes in the terminology, which were accepted by Dr. Lamb for the Committee. On motion of Dr. Huntington, the Association ordered that copies of the report should be printed and distributed among the members for their information and criticism along with the statement that the *terminology* should not be considered as necessarily being that which the Association might ultimately recommend.

On motion of Dr. Huntington, the annual dues were increased to three dollars; the increase to begin with the year 1897–98.

Dr. Huntington, of the Medical Department of Columbia University, New York City, then made remarks on 'Corrosion Anatomy, Technique and Mass ;' illustrated by the material and specimens. The subject was discussed by Drs. Wilder and Dawbarn.

Dr. Lamb showed the following specimens and made remarks on the same: Specimen of fissured sternum ; two specimens of sterna of young children; an extra carpal bone; bilateral bony ankylosis of jaw; and a penis, showing exaggerated papillæ on corona. Discussed by Drs. Wilder, Dawbarn, Gill, Baker and Huntington.

A paper by Dr. B. B. Stroud, of Cornell University, on 'Comparative Anatomy of the Cerebellum' was, in Dr. Stroud's absence, read by Dr. Wilder. It was illustrated by photographs and charts. Discussed by Drs. Gill, Baker, Huntington and Wilder.

At the meeting on May 5th Dr. Gerrish was elected as a member of the Executive Committee, to fill the vacancy made by the retirement under the constitution of Dr. Gill.

The Secretary stated that after the adjournment the previous day there was a consultation of several members and it was thought appropriate to send to Dr. Allen, who had just undergone an operation for appendicitis, a telegram conveying the sympathy and good wishes of the Association. The Secretary had sent the telegram. On motion of Dr. Wilder this action was approved.

Dr. Wilder then made remarks on 'The Definitive Encephalic Segments and their Designation.' Illustrated by photographs and charts. Discussed by Drs. Gill, Gerrish, Carr, Baker and Huntington. In connection with this subject Dr. J. A. Blake showed photographs of a brain with double precommissure.

Dr. Woods Hutchinson, of Buffalo, read a paper on 'A Possible Morphologic Basis for Diseases of the Lungs.' Discussed by Drs. Huntington and Baker.

The paper of Dr. Stroud on 'Brain Preservation' was read by title.

Dr. Huntington made remarks on 'Ventral Version of Secondary Fore-brain.' Illustrated by photographs. Discussed by Dr. Wilder.

Dr. William Browning, of Brooklyn, read a paper on 'Examination of Spinal Efferents for the Cerebro-spinal Fluid. Discussed by Drs. Wilder and Baker.

Adjourned.

At 5 p. m. the statue of Prof. Dr. Samuel D. Gross in the Smithsonian Park and

near the Army Medical Museum was unveiled with appropriate ceremonies, and at 8:15 p. m. the President of the Congress, Prof. Dr. Wm. H. Welch, of Johns Hopkins University, Baltimore, delivered the Presidential address, which has been published in SCIENCE.

On May 6th the Executive Committee, through the Secretary, reported a recommendation that the next meeting of the Association should be held at Cornell University in December, 1897, in conjunction with the Society of American Naturalists and other affiliated societies. On motion the Association adopted the report.

The President called attention to the fact, that inasmuch as the Congress met every three years, the election for delegate to its Executive Committee every two years seemed to cause some confusion. After some discussion Dr. Hewson moved that hereafter the election for delegate occur every *three* years, and this was adopted. Dr. Wilder, from the Committee on Anatomical Nomenclature, reported progress. Report accepted. Dr. Gerrish, from the Committee auditing the Treasurer's account, reported the accounts correct.

Dr. Huntington made remarks on 'The Cerebral Convolutions of two Brains from Natives of British Guiana.' Illustrated by casts and photographs. Discussed by Drs. Baker and Wilder.

Dr. F. J. Shepherd, of Montreal, showed a specimen of double internal cuneiform bone of right foot of a white woman aged 17; and photographs of hands and feet of same subject, showing multiple digits.

Dr. W. P. Carr, of Washington, showed some anatomical models on a large scale illustrating the circulation of the blood through the heart, the formation of a blood-vessel, and the corona radiata. Discussed by Drs. Wilder, Huntington and Shepherd.

Dr. Blake read a 'Contribution to the Topographical Anatomy of the Mediastinum Superior Theoracic Aperture.' Discussed by Drs. Baker, Wilder and Huntington.

Dr. Addinell Hewson, of Philadelphia, showed the forms of record used in the dissecting rooms of Jefferson College, Philadelphia, Pa., and made remarks thereon. Discussed by Drs. Baker, Huntington, Reisinger and Wilder.

Dr. C. A. Hamann, of Cleveland, showed specimens of congenital malformation of the extremities. Discussed by Drs. Huntington and Geo. T. Kemp.

The Association then adjourned *sine die*.

After the adjournment, at the suggestion of Dr. Kemp, Dr. G. C. Huber, of the University of Michigan, exhibited slides showing the terminal endings of the nerves in the epithelium of the urinary bladder and the sensory nerve endings of the muscle.

D. S. LAMB,
Secretary.

*SYSTEMATIC CLASSIFICATION OF TEXTILE AND OTHER USEFUL FIBERS OF THE WORLD.**

THE advantages of a broader and more systematic classification for textile and other useful fibers has long been appreciated by the author. While engaged in the preparation of a descriptive catalogue of fibers of the world in which over a thousand species of useful fiber plants are enumerated, the necessity for a better classification became apparent, and the scheme herewith presented was devised. The term fiber is popularly understood to relate to those forms of filamentous substance that can be spun and woven, or twisted into cordage, though it should not be employed in so restricted a sense. In fact, many of the true fibers are used in other ways, for there are kinds of cordage, and even cloth substi-

*Abstract of a paper read before the Philosophical Society of Washington, by Chas. Richards Dodge.

tutes, that are neither spun or woven. On the other hand, there are many forms of fibrous substances of the roughest description, such as reeds or shredded palm leaves, that are plaited, this being a coarse form of weaving, so that it becomes difficult to draw the line between a fine spinning fiber like flax, that is woven into linen fabrics, and a sedge, coarsely woven into matting, or a woody twig of Salix plaited into a basket.

In the classification proposed two groups are recognized, based on cell structure. The first, fibers with fibro-vascular structure, embraces three sub-groups, and the second, fibers with simple cellular structure, embraces two sub-groups. The classification is as follows:

A. FIBRO-VASCULAR STRUCTURE.

1. Bast Fibers:

Derived from the inner fibrous bark of dicotyledonous plants or exogens, or outside growers. They are composed of bast cells, the ends of which overlap each other so as to form, in mass, a filament. They occupy the phlöem portion of the fibro-vascular bundles, and their utility in nature is to give strength and flexibility to the tissue.

2. Woody Fibers:

a. The stems and twigs of exogenous plants, simply stripped of their bark and used entire, or separated into withes, for weaving or plaiting into basketry.

b. The entire, or subdivided *roots* of exogenous plants, to be employed for the same purpose, or as tye material, or as very coarse thread for stitching or binding.

c. The *wood* of exogenous trees easily divisible into layers or splints for the same purposes, or more finely subdivided into thread-like shavings for packing material.

d. The *wood* of certain soft species of exogenous trees after grinding, and converting by chemical means into wood pulp, which is simple cellulose; and similar woods more carefully prepared for the manufacture of artificial silk.

3. Structural Fibers:

a. Derived from the structural system of the stalks, leaf stems and leaves, or other parts of monocotyledonous plants or inside growers, occurring as isolated fibro-vascular bundles, and surrounded by a pithy, spongy, corky, or often a soft, succulent, cellular mass covered with a thick epidermis. They give to the plant rigidity and toughness, thus enabling it to resist injury from the elements; and they also serve as water vessels.

b. The whole stems, or roots, or leaves, or split and shredded leaves of monocotyledonous plants.

c. The fibrous portion of the leaves or fruits of certain exogenous plants when deprived of their epidermis and soft cellular tissue.

B. SIMPLE CELLULAR STRUCTURE.

4. Surface Fibers:

a. The down, or hairs surrounding the seeds, or seed envelopes, of exogenous plants, which are usually contained in a husk, pod or capsule.

b. Hair-like growths, or tomentum, found on the surfaces of the stems and leaves, or on the leaf buds of both divisions of plants.

c. Fibrous material produced in the form of epidermal strips from the leaves of certain endogenous species, as the palms.

5. Pseudo-Fibers, or False Fibrous Material:

a. Certain of the mosses, as the species of *Sphagnum*, for packing material.

b. Certain leaves, the dried substance of which forms a more delicate packing material.

c. Sea weeds wrought into lines or cordage.

d. Fungus growths, or the mycelium

of certain funguses that may be applied to economic uses for which some of the true fibers are employed.

In the portion of the paper which followed, the different forms of fibers were defined in detail and examples given from the list of well-known commercial and native or aboriginal species. It is the consideration of these useful native fibers that makes it possible to enumerate a list of a thousand species of fibrous plants, while the world's commercial fibers would hardly reach a total of fifty species. The native or aboriginal forms are interesting; our museums are filled with manufactures from them, and any scheme of systematic classification which omits them is faulty and imperfect.

CURRENT NOTES ON ANTHROPOLOGY.

PIGMENTATION OF THE SKIN.

M. Breul, in an inaugural thesis reviewed in *L'Anthropologie*, reports some new observations on the pigmentation of the human skin.

The colors of the different races depend upon this pigment in the epidermis, especially in its deeper strata. Breul finds the coloring matter in the interior of the epithelial cells, while even in the negro the intercellular spaces are white. The pigment itself may be quite black, or of any shade up to a light yellow. It may be confined to the nucleolus, or extend over the cell. A close examination shows that it is distributed in patches over the skin, between them the tissue being colorless. This is true even of the black races, although in them the patches are close together and may not be discernible unless the skin be stretched.

This distribution of the coloring matter is the same in all races. and its actual amount is probably the same, the difference in hue resulting from the darker or lighter character of the pigmentary grains.

HOLMES' RESEARCHES IN MEXICO.

The second part of the 'Archæological Studies' of Professor William H. Holmes (for a notice of the first part, see Science, February 21, 1896) is devoted to the 'Monuments of Chiapas, Oaxaca and the the Valley of Mexico.' It is a most attractive monograph, based on original personal studies, and containing nearly forty full-page plates, panoramic views and numerous text illustrations. The ruins described are those of Palenque, Monte Alban (in Oaxaca), Mitla and San Juan Teotihuacan. The volume closes with a series of 'Studies of Ancient Mexican Sculpture,' referring to tablets, yokes, figures and carved shells.

The text is full of new suggestions and comparisons, as well as of facts. The architectural elements of the various sites are analyzed and compared, and the sources from which the materials were obtained were carefully sought out. Nowhere was any evidence found of the use of metals, or a condition of the arts above that known to have existed at the discovery, although the stately monuments of Oaxaca and Teotihuacan testify to an astonishing concentration of effort for prolonged periods. The remains in Mexico are more magnificent in dimensions, but on the whole less artistic than those of Yucatan or Chiapas.

D. G. Brinton.
University of Pennsylvania.

NOTES ON INORGANIC CHEMISTRY.

In the last *Comptes Rendus* a new atomic weight determination of cerium is described by Wyrouboff and Verneuil. The element was obtained in a state of great purity, and the determinations made by converting the sulfate into the oxid by heat. The atomic weight is given at 92.7, but this is on the supposition that the oxid obtained is Ce_3O_4. It is ordinarily considered that the formula of this oxid is CeO_2, which would

give an atomic weight of 139.05, or about one unit lower than the best previous determination. According to this last weight, cerium is a member of the first series of Mendeleff's fourth group, and to this the oxid CeO_2 corresponds. It is true that many of the properties of cerium do not agree well with this position, but the atomic weight of 92.7 can hardly be brought into harmony with the periodic system, as there is no vacant place between zirconium (90.4) in the fourth group and columbium (93.7) in the fifth group.

E. CHUARD, in the *Comptes Rendus*, suggests the use of calcium carbid as a phylloxericide. The presence of phosphorus in the carbid is advantageous, as the phosphocarbid possesses exceptionally powerful insecticidal properties, probably owing to the generation of acetylene rich in phosphin, or possibly containing a phosphorus-carbon compound.

A RECENT number of *Nature* contains a notice, taken from the Journal of the Russian Physical and Chemical Society, of the death of Dr. Véra Bogdanovskaya-Popoff, who was killed on May 8th in her laboratory at Izhora by an explosion. She had been working to obtain a compound of carbon and phosphorus, analogous to prussic acid, but with phosphorus in the place of nitrogen, and it was while engaged in this dangerous investigation that the fatal explosion occurred.

IN a paper read before the Royal Society on June 17th, W. J. Russell describes the action excited by certain metals and other substances on a photographic plate. Experiments showed that uranium salts and oxids act slowly on photographic plates in the dark; this property is shared by metallic zinc, cadmium and magnesium, as well as many other substances, as copal, strawboard, wood, some kinds of paper. This action was at first supposed to be contact action, and then it was thought that in the case of metals minute emanations might be given off. This, however, is negatived by the fact that zinc acts equally well when not in contact with the plate, and even when completely insulated by a coating of varnish.

THE June Journal of the Chemical Society contains a paper by Dr. John Ball on the circumstances which affect the rate of solution of zinc in dilute acids, with especial reference to the influence of dissolved metallic salts. It is a familiar fact that the action of pure zinc on sulfuric acid is very slow, but may be greatly accelerated by the addition of certain metallic salts. Platinic chloride is generally used for this purpose, and less frequently a cobalt salt. Dr. Ball finds that with sulfuric acid, magnesium or aluminum sulfate have no accelerating influence, that of chromium, manganese and iron is very slight, silver is greater, while cobalt, copper and nickel sulfates have great influence and in this order. The relative maximum velocity of solution, taking the velocity of pure sulfuric acid as unity, is for the addition of silver sulfate, 9; cobalt sulfate, 18; copper sulfate, 21, and nickel sulfate, 38. In the case of solution in hydrochloric acid the addition of manganese, lead or tin chloride had but little influence, copper somewhat greater (11), while the relative velocities for cobalt, gold, platinum and nickel were respectively 31, 39, 42 and 45. It will be seen that with both acids the addition of a nickel salt causes the greatest acceleration, and the relative order of the different methods is approximately the same, except that copper has much less influence on the solution in hydrochloric acid. Dr. Ball presents no theory of the reaction, but it is a fact worthy of note that in the case of the two metals having most decided influence, nickel and cobalt, it could not be detected that any metal was deposited on the zinc, thus forming a couple.

J. L. H.

PHYSICAL NOTES.

THE 'DARK LIGHT' OF M. LE BON.

During the past two years M. Gustav Le Bon has brought out a remarkable fact regarding the passage of light through metals and other so-called opaque substances. This fact, so far as it can be estimated from a study of Le Bon's and others' published results, without resort to confirmatory experimentation, is either that the extreme red or infra-red components of sunlight and of gas light pass through thick metal plates sufficiently to affect sensitive plates after prolonged exposure; or that the medium wave-length components of sunlight and of gas light excite hyperphosphorescence in such metals as copper and lead just as they are known to do in case of uranium as shown by Becquerel. It seems that Le Bon in his experiments has eliminated the effects of direct pressure upon the sensitive film, the effects of temperature and such effects as might be due to chemical action between the film and the metal screens.

In the exposition of his results Le Bon is unsatisfyingly fragmentary and vexatiously notional, and it is amusing, at best, to read his claim of a new connecting region between light and electricity—*la lumière noire.* "Elle ne se propageait peut-être plus comme la lumière et peut-être propageait-elle comme l'électricité." So far as known, 'electricity,' when it is propagated at all, is propagated in a manner identically the same as light, and a fancied difference is of no use in setting forth results. Facts are plain, new facts utterly so, and a discoverer who would have it appear otherwise is either not a discoverer or does not know himself to be one. W. S. F.

SCIENTIFIC NOTES AND NEWS.

The Weights and Measures (Metric System) Bill passed through the Standing Committee on Trade of the British House of Commons on July 5th, and was ordered to be reported without amendments.

A bronze monument of Père Marquette, the priest and explorer, was unveiled in Marquette, Mich., on July 15th.

A monument in honor of Daguerre, erected by public subscription, was unveiled at Bry-sur-Marne on June 27th.

The Paris Academy has elected Professor Virchow as a foreign associate in the room of the late M. Tchebitchef. The other nominees were Lord Rayleigh, as second choice, and, as third choice, Professors Schiaparelli, Stokes and Suess.

The Right Honorable Leonard H. Courtney, M. P., has been elected President of the Royal Statistical Society.

The Royal Society of Edinburgh has awarded the Gunning Victoria Jubilee Prize to Mr. John Aitken, the Keith Prize to Dr. Kargill G. Knott, the MacDougall-Brisbane Prize to Professor J. G. M'Kendrick and the Neill prize to Mr. Robert Irvine.

It is stated in the Washington *Star* that M. Zolla has been sent to America by the French government to study methods of agriculture.

The subject of the essays for the Howard Medal and Prize of the Royal Statistical Society for 1898 is 'The treatment of habitual offenders, with special reference to their increase or decrease in various countries.'

A meeting was held on July 2d, at University College, London, to inaugurate the memorial to the late Sir John Pender, to which we have already referred. Remarks were made by the chairman, the Marquis of Tweeddale, by Mr. Haldane and by Lord Kelvin. A check for £5,000 was presented by the chairman to the authorities of University College to endow the electrical laboratory, and the bust of Sir John Pender was exhibited. Lord Kelvin spoke of what Sir John Pender had accomplished. When the first experiment was made to lay a cable across the Atlantic, Sir John Pender was one of the directors of the company. When the temporary success was followed so soon by

failure, the directors resigned one after the other, and it was due to Sir John Pender alone that the undertaking was not abandoned in the period from 1858 to 1864.

WE regret to record the deaths of Samuel Brassai, professor of mathematics at Klausenberg, at the age of one hundred years; and of Dr. H. Wankel, of Olmütz, known for his researches in anthropology and archæology.

THE Librarian of Congress has made several excellent appointments, but has offered the position of chief of the art department of the Congressional Library to a newspaper correspondent. It is, perhaps, thought that connection with the New York *World* gives an adequate training in modern art.

THE government of La Plata has made arrangements for securing the services of a bacteriologist whose duty it shall be to make an experimental study of tropical epidemics.

MESSRS. KADY, Berg and See, architects, have submitted to the Department of Buildings, New York, plans for two additions to the American Museum of Natural History, one a lecture hall at the north end of the Museum to cost $150,000, the other a six-story building attached to the west wing to cost $400,000.

THE Boissier Herbarium at Chambésy, near Geneva, which recently acquired the books on lichens and the dried specimens of the late Dr. J. Müller, is, according to *Natural Science*, following the example of the trustees of the Tuckerman Memorial Library of Lichenology, Amherst, Mass., and has established a 'Lichenotheca Universalis Müller-Argau.' The curator, M. Eugene Autran, appeals to botanists for copies of publications bearing on lichens and also for specimens of new and rare species.

THE Prince of Wales Hospital fund had, up to the beginning of the present month, received donations amounting to about £130,000 and promises of annual subscriptions amounting to about £2,500. The hospital Sunday fund is, however, this year smaller than usual. It is stated that Americans resident in England have endowed with £1,000 each beds in five London hospitals, to be used in the first instance by Americans.

SIR ANDREW NOBLE has given £100 to the Royal Institute, London, for the fund for the promotion of experimental research at low temperatures.

THE State Department has transmitted to Congress a copy of the note from the Minister of Norway and Sweden, inviting the United States government to participate in the International Fisheries Exposition to be held at Bergen, Norway, May 16th to September 30, 1898, with a recommendation that an appropriation be made for this purpose.

THE seventh annual meeting of the Paris Society of Hypnotism and Psychology was announced for July 19th, under the presidency of M. Dumontpallier.

THE eighteenth annual meeting of the German Anthropological Society will be held from the 3d to the 5th of August at Lübeck. Excursions are arranged to Schwerin and to Kiel on the days following the meeting.

THE Board of Directors of the American Chemical Society have authorized the establishment of a local section at Columbus, O., the necessary steps having been taken as required by the constitution of the Society.

IT can scarcely be hoped that the letter addressed by the Secretary of State to the Ambassador at London, and for some inexplicable reason published in the daily papers, will conduce to a scientific solution of the question of the results of pelagic sealing in the Bering Sea. It is unfortunate when scientific testimony is used for conflicting political interests. It would apparently have been best for the British and American scientific experts to have drawn up a joint report containing only the facts on which they were agreed.

THE daily papers contain accounts of the arrival of a steamship from the Yukon district of Alaska, reporting great success in the Klondyke gold fields. It is reported that single individuals have taken out in two and a-half months more than $150,000 in gold.

THE steamer Svensksund has reached Norway from Spitzbergen with the news that Herr Andrée and his companions began their voyage on July 11th, at 2 : 30 p. m. The balloon was carried in a northeasterly direction.

A conference was held in the rooms of the Royal Geographical Survey, on July 5th, for the purpose of promoting Antarctic exploration. The chief object of the meeting was to bring the matter to the attention of the Australasian Premiers, then in London, with a view to inducing them to secure from their governments contributions toward a British Antarctic Expedition, under the auspices of the Royal Geographical Society. Sir Clements Markham, President of the Society, the Duke of Argyle, Sir Joseph Hooker and Professor Rücker made addresses urging the great scientific importance of exploring the South Polar regions. The Australasian Premiers were, it appears, unable to be present, but replies were made by representatives of New South Wales, Victoria and New Zealand, favoring the plan. The President said that he had been authorized to state that the Council of the Society would contribute any sum up to £5,000 which the colonial governments might subscribe.

The London *Times* states that Sir Martin Conway and Mr. E. J. Garwood left London on June 29th for Spitzbergen, in order to continue the exploration of the interior of the main island begun by them last year. They are to be landed at King's Bay, whence they hope to make sledge expeditions over the northern ice sheet. Afterwards they intend to revisit Horn Sound and complete the scientific exploration of the southern peninsula.

The London correspondent of the New York *Evening Post* cables that Mr. George Murray, keeper of botany in the British Museum, has proceeded to Panama at the instance of the government grant committee of the Royal Society for researches on little known pelagic algæ. During the voyage these organisms will be obtained by pumping sea water through fine silk tow nets.

Mr. Geo. H. Eldridge, of the Geological Survey, has completed the field investigation of the phosphate deposits of Florida, and returned to the Washington office to prepare his report. This investigation was one of considerable magnitude, Mr. Eldridge having spent one year and nine months in actual field work.

The Peary party includes, through arrangements made by Professor C. D. Walcott, Mr. Chas. Schuchert, from the U. S. National Museum, and Mr. C. David White, from the U. S. Geological Survey. They will disembark at Disco Island, off the western coast near the 70th parallel, and this island and the mainland immediately adjacent will be their field of work. Mr. Schuchert, who is in charge of the Department of Invertebrate Paleontology in the National Museum, will go in quest of Mesozoic and Tertiary fossils, and Mr. White, who is one of the paleobotanists of the Geological Survey, expects to make a large collection of the Mesozoic and Tertiary plant remains of the region visited. America has thus far secured but meager collections of polar fossils, Europe being far ahead in this regard. Mr. Robert Stein, of the Geological Survey, also accompanies the expedition, but not as an official representative of the bureau. He will leave the party at Wilcox Head, from which point he expects to make a survey of the coast north of Devil's Thumb, toward Melville Bay.

M. Marey has contributed to the Paris Academy an account, by MM. V. Tatin and Ch. Richet, of trials of an aëroplane invented by them. Their first experiments were made in 1890, but the machine was wrecked. A new machine was then constructed, with which the first trial was made last year with some success. In a second trial in June last the aëroplane travelled through the air 170 m. at the rate of 18 m. per second. The machine weighed 33 kg. The authors compare their results with those obtained by Professor Langley, and, while admitting the greater distance traveled by the aerodrome, claim that their machine had the advantage of greater weight and greater speed.

At the Royal Naval Review the performances of the *Turbinia*, a boat in which the Hon. C. P. Parsons has made use of the steam turbine for marine propulsion, excited much attention. It steamed at a speed of 34 knots an hour, and it is said that even yet the full power has never been applied.

At the recent International Congress of Publishers at Paris the inexactness of designating the size of books as 4°, 8° and 12° was dis-

cussed, and a resolution was passed to the effect that catalogues of publishers should give the actual sizes of volumes in the metric system.

THE second interim report of the departmental committee appointed by the British Home Office to inquire into and report on certain dangerous trades has just been issued as a Parliamentary paper. This report, which is signed by all the members of the committee, including the additional member, Mr. C. V. Boys, F.R.S., deals with electrical generating works. According to the London *Times* the committee has framed several regulations which they recommend should be applied in all cases where electricity at high pressure—a direct current of 700 volts or more, or an alternating current of 350 volts—is in use. The recommendations include the following regulations: The frames and bed-plates of all generating machines shall be efficiently connected to earth. The rails fencing dynamos or other generating machines shall be made of wood or other non-conducting material. The floors of all places where it would be possible to make connection with metal at high pressure should be covered with an insulating mat of suitable material and kept in a state of efficient insulation. In switchrooms and on the front of switchboards the main switches, main fuses, main terminals, omnibus bars and all other metallic parts shall be insulated or arranged in such a manner as to render it impossible for any person by accident or inadvertence to touch them. All switchboards erected after the application of these rules shall have at the back a clear space of at least four feet. This space shall not be utilized as a store room or lumber room, or be obstructed in any manner. Any person at work upon a cable or portion of the mains under high pressure shall wear india-rubber gloves on both hands, and the gloves shall be supplied by the occupier, and it shall be the duty of the manager to see that they are in a proper state of repair and are worn by the work people.

THE twenty-second annual report from the Savilian professor of astronomy at Oxford, Mr. H. H. Turner, is published in the *University Gazette* for June 23d. It is stated that the measurement and reduction of the plates for the Astrographic Chart has been the staple work of the year. The Royal Society having granted £150 from the government grant fund during the year, four or five boys who have just left school have been engaged to carry out the measures and reductions under the supervision of the assistants, and the experiment has been successful, one-tenth of the whole work having been accomplished in the last six months. The need of a residence at the observatory pressed on the attention of the board at their last meeting, and fully recognized by them, has not been acknowledged by the Hebdomadal Council. In journeying across America to and from Japan, in order to observe the total solar eclipse of August 9th, the Astronomer Royal, Captain Hills, R. E., and Professor Turner took the opportunity of visiting several Canadian and American observatories. Professor Turner acknowledges the courtesy shown to him, especially at Montreal, Chicago, Cambridge and Washington. "It would be ungrateful not to add that what we saw was of immense value to us, in the way of suggestion; the ideas acquired at the Harvard observatory alone were worth the journey, and cannot fail to leave their impress on the work here."

THE report of Dr. Gill for the year 1896, to the Lords Commissioners of the Admiralty, is abstracted in a recent issue of *Nature*. The McLean telescope is expected to be completely installed and in full working order before the end of the present year. During the last few years Dr. Gill has somewhat necessarily restricted the amount of observational work in order to make more progress in the computation and publication of many arrears, and it is satisfactory, then, to hear that it has now become possible to again resume a program of activity. Several important publications have been concluded in the last twelve months. Among them may be mentioned Vol. II., containing a determination of the solar parallax and mass of the moon, from observations of Iris, Victoria and Sappho, made in the years 1888 and 1889. Vol. I. is also practically complete. The first volume of the Cape Photographic *Durchmusterung* is also ready for distribution, Vol. II. being in course of printing. The observational work with the transit circle, equatorials and astro-

photographic telescope has been very considerable, and it may be mentioned that all the catalogue plates, with the last-mentioned instrument, have now been obtained. Out of the 230 chart plates, 169 have been satisfactorily exposed. The 7-inch equatorial has also been very busy in the hands of Mr. Innes, and, besides several new variables, 104 new double stars have been discovered. Dr. Gill refers also to the increase in staff and the necessity for a reversible transit circle for refined fundamental work, and mentions that these proposals have been favorably considered by the Lords Commissioners of the Admiralty and of Her Majesty's Treasury.

A CONVERSAZIONE was given by the President and Council of University College, London, on June 30th. According to the account in the London *Times* there were a large number of interesting exhibits. Professor Percy Gardner showed a series of archæological photographs, and Mr. Seton-Karr the interesting collection of flint implements recently discovered by him in Somaliland and Egypt. In the mechanical engineering laboratory all the machinery was in motion, besides a number of machine tools lent by various firms. In the electrical laboratory Professsor Elisha Gray's writing telegraph, by which writing may be transmitted long distances, was shown in operation by the Telautograph Company. Messrs. Harvey and Peek gave an exhibition of Tesla experiments with high-frequency currents, and Mr. J. W. Swan sent some of his experiments on electrical discharges against insulators in which curious frond-like figures were produced by the electric spark, and also a delicately-poised Gramme ring which rotated under the influence of the earth's magnetism. In the applied mathematics department apparatus and diagrams were on view illustrative of the work done and the methods of study pursued. These included various calculating machines, instruments for finding areas, and models illustrating games of chance and statistical variation and correlation. There was also a fine collection of books (mainly from the Graves Library of University College) and of portraits illustrating the history of pure and applied mathematics. In the physical lecture room experiments were shown with Hertzian waves and with the magnetic deflection of cathode rays, while Professor Ramsay exhibited the spectra of argon and helium. Some beautiful collections of begonias, orchids, roses and other flowers were to be seen in the anatomical museum, together with a collection of dwarf Japanese trees, some of them being a century old and yet only a foot or so high. Not the least attraction of the evening was Professor Flinders Petrie's exhibition of Egyptian antiquities, which includes the results of recent excavations at Deshasheh, Behnesa and El Kab.

IN one of the Harben lectures given on June 30th, at Kings College, London, Dr. Sims Woodhead discussed the antitoxin treatment of diphtheria. The London *Times* states that he showed examples of the degeneration of tissue produced in various organs of the body, even so soon as the third or fourth day of the disease, and pointed out that after these changes had occurred the physician could not expect to bring the patient back to health at once. This consideration explained the diminished curative power of the antitoxic serum in the latter stages of the disease. The life of a patient depended on the tissues being able to carry on their work, and they could do this if the action of the toxin on their cells could be prevented. In the presence of both toxin and antitoxin these dreaded organic changes did not occur. Hence, if a patient was to recover, antitoxin must be present, whether it was formed within the body or injected from the outside. The serum had both a preventive and curative action, and he would not hesitate to recommend its use as a prophylactic for people exposed to infection. As regards its remedial use the question of time was most important. The necessity of an early exhibition of the serum was illustrated by some statistics. In 1894, before the antitoxin treatment was adopted, the mortality of cases of which the treatment was begun on the first day of the disease was 22.5 per cent.; in 1896 it fell to 4.7 per cent. Of cases of which the treatment was begun on the second day the percentage of mortality decreased from 27 in 1894 to 12.8 in 1896, while in those which came under treatment in the third day the mortality was 29.4 in 1894 and 17.7 in 1896. Even in cases which were neglected till

the fifth day the antitoxin treatment effected a reduction of 6.2 per cent. in the mortality. In view of these figures, and of others dealing with the death-rate in post-scarlatinal and laryngeal cases, Dr. Woodhead expressed his strong conviction that those who opposed the use of the remedy assumed a tremendous responsibility.

MR. ALEXANDER WATT contributes to the last number of the *Bulletin de l'Institut International de Bibliographie* (why should a journal devoted to bibliography omit the date of issue?) an account of a new form of card catalogue. The usual plan of arranging a card catalogue is to place the cards in a drawer or box, a rod being run through the holes in the cards to keep them in their proper order. The examination of the catalogue is made by turning over the cards as one would turn the leaves of a book if it were laid upon its back with its fore-edge in front of the examiner. There are several inconveniences arising from this method of keeping cards. (1) A special cabinet of drawers or boxes is required. (2) As the drawers are bulky and expensive they are generally made too large (to reduce the bulk and expense), which prevents the catalogue being consulted by more than one or two persons at once. (3) It is difficult to keep a particular card in view during the copying of a title, and only one card can be readily seen at a time. In order to obviate these disadvantages Mr. Watt has devised a new receptacle for holding the cards, consisting of a case made in the form and of the materials of the boards of a book. The cards are placed between the boards of the case and are held in position by means of a pin passing through the *outer* corner of the cards and case. The pin, which is made to exactly fit the hole in the cards, has a fixed hole at one end and at the other end a head which screws into the pin. The cards during examination, instead of sliding along the pin, are rotated on it outwards *en bloc*, and may be spread out in the form of a fan so as to keep in view several cards at the same time. As the cards are examined they are pushed back into the case, one or more at a time. As the cases (which may be made of any thickness) when full of cards look like ordinary books they may be arranged like them on the shelves, and as they can be made very cheaply the catalogue of a library may be split up into hundreds of volumes, which will thus allow of its being consulted by many persons at the same time.

THE *Engineering and Mining Journal* has compiled its fifth annual volume on the mineral industry of the United States, giving statistics for the year 1896. The total value of the production was $706,015,411, an increase of $23,950,-293 over the preceding year. The United States in 1896 was the largest gold producer of the world and the largest silver producer; it was also by far the largest producer of copper, furnishing over one-half of the world's supply of that metal. Notwithstanding the decrease in the pig iron output it was still larger than that of any other country. In coal the total was still less than that of Great Britian, though it is gradually approaching the point where the two will be equal. The editor writes: "In accordance with our usual custom, we have added to the usual measurements of quantities in each case the metric measures, which we earnestly hope will soon be the only legal measure in this country, as they already are in nearly every other civilized country."

THERE was recently an interesting debate in the British House of Lords regarding works of art and the finance act. A clause in that act enacted last year reads as follows:

"Where any property passing on the death of a deceased person consists of such pictures, prints, books, manuscripts, works of art, scientific collections, or other things not yielding income as appear to the Treasury to be of national, scientific or historic interest, and is settled so as to be enjoyed in kind in succession by different persons, such property shall not, on the death of such deceased person, be aggregated with other property, but shall form an estate by itself, and while enjoyed in kind by a person not competent to dispose of the same be exempt from estate duty; but if it is sold or is in possession of some person who is competent to dispose of the same shall become liable for estate duty."

This clause it appears has been interpreted so as to include only works of art, illustrating English history. It is not clear whether scientific collections must also be confined to English history in order to be exempted from death dues. It was claimed in the debate in the

House of Lords that the tax leads to the dispersion of art collections, pictures being exported from England to the value of $6,000,000 annually.

The *British Medical Journal* states, on the authority of the Secretary of the Pretoria Agricultural Society, that Professor Koch's results with rinderpest inoculation are better than usually stated to be. He says that the method carried out in hundreds of instances has proved successful, but the unfortunate part has been that the ignorant Boer has not carried out all the particulars as instructed. He knew of one instance in which a Boer, after inoculating an animal with the virus, actually cleaned his fingers on the back of the nearest one grazing. In his opinion, however, it is not quite possible to stamp out the disease by the method, as it is impossible to inoculate throughout South Africa the hundred thousands of heads of cattle belonging to the natives in isolated districts in various parts of the country, and this contagious virus is, moreover, carried by the aasvogels (a species of vulture), who feed on the carcasses and carry the rinderpest from farm to farm.

It is stated in *Nature* that a botanical society has recently been established at Perth, West Australia, and has been given the designation of the Mueller Botanic Society, as a tribute to the memory of the late Baron von Mueller, who spent the best part of his life in investigating the plants and other products of Australia. Sir John Forrest has been elected President of the new Society; Mr. Wittenoom and Mr. Leake, Vice-Presidents, and Mr. Skews, Secretary.

The Auckland Institute, says *Natural Science*, has decided to add a new hall, 50 feet square, to its Museum, on the east side of the Ethnographical Hall. It is intended to receive the statuary presented by Mr. T. Russell, which has hitherto found an uncongruous home among stuffed vertebrates. The space thus gained will be occupied by groups of the larger mammals, and £100 offered by Mr. Russell will be used to procure a group of the larger carnivores. Little Barrier Island, on which an attempt is being made to preserve the indigenous fauna and flora of New Zealand, has been placed under the control of the Institute, with a grant of £200 for the first year's expenses. Mr. R. H. Shakespear has been appointed curator, and it is hoped that he may be able to stop the depredations of collectors.

UNIVERSITY AND EDUCATIONAL NEWS.

It is announced that a college for women under the auspices of the Roman Catholic Church will be established at Washington. It will be called Trinity College, and will be adjacent to the Catholic University of America.

The municipal council of Marseilles has passed a resolution favoring the establishment of a university in that city.

Mr. C. L. Herrick, lately professor of biology at Denison University, has been elected President of the Territorial University at Albuquerque, New Mexico.

Dr. A. R. Hill has been appointed professor of psychology and ethics in the University of Nebraska, and Dr. E. L. Hinman has been promoted to an adjunct professorship of philosophy in the same University.

Miss Bertha Stoneman, who has been engaged for several years in the study of the development of fungi in the botanical department of Cornell University, and who received last year the degree of Doctor of Philosophy, has been appointed professor of botany in the Huegenot College in Cape Colony, South Africa. This is a college for the education of the daughters of the French and Dutch Huegenots and English residents in South Africa. She sails from New York on Saturday, July 24th, for Liverpool, and thence by the British African line of steamers for South Africa.

Miss Arma Anna Smith, M. S., and Miss Ethel Muir, Ph.D., both of Cornell University have been appointed assistants in Mount Holyoke College, South Hadley, Mass., the former in botany and the latter in philosophy.

Miss Ellen Hayes, for the past nine years professor of mathematics in Wellesley College, has just been made professor of applied mathematics in the same College. The courses of

study conducted by Miss Hayes include mechanics, thermodynamics, geodynamics and theoretical astronomy.

PROFESSOR HUGO DE VRIES, of Amsterdam, has been called to the chair of botany in the University of Würzburg as successor to the late Professor J. Sachs. In the same University, Professor Ph. Stohr, of Zurich, has been appointed professor of anatomy in succession to Professor v. Kölliker, who will hereafter confine himself to histology and embryology. Dr. Salomon has qualified as docent in geology and mineralogy in the University at Heidelberg.

DISCUSSION AND CORRESPONDENCE.

NEW TERMS IN GEOLOGY.

PROFESSOR DAVIS, speaking in behalf of new terms in geology and geography (SCIENCE, July 2, p. 24), makes the following points: that new terms are necessary to any advancing science; that new things and new ideas must have new names, and that the investigator must be left as free to name his conclusions as to reach them. He mentions some terms introduced by Powell in 1874 as examples of useful ones, and others of later introduction which he expects to see survive; at the same time he admits that he has been not a little amused at watching the rest of us 'wrestle' with new terms.

These contentions seem at first glance to be altogether reasonable. But that new terms are demanded by an advancing science is admissible only in a limited sense. The discovery of new elements, new materials, new biologic forms, all call for new names. To these no one thinks of objecting. Aside from such cases, what book published in the last fifty years has contributed more than any other to the advance of science all along the line? Darwin's 'Origin of Species.' And how many new terms did Mr. Darwin use? Not one—if we except such an expression as 'natural selection.'

The newest science of which I have any knowledge is that now being remarkably developed by Dr. Charles H. Gilbert, of Stanford University, in studying geographic and geologic changes by means of the fish faunas. And I venture to say that his splendid results will eventually be brought forth, not dressed in the paraphernalia of a new terminology, but without the use of a single new expression.

It certainly does not follow, then, that an advancing science and new ideas must, of necessity, have new names.

As for freedom to name one's conclusions, I would ask: Is this naming a matter that concerns the finder alone, or does it concern every one who has to do with the science? Are facts and conclusions private property to be named, like one's dog, as the owner happens to fancy, or are they a part of science, and to be named with some reference to those who may have to use them?

Mention is made of certain geographic terms that are expected to prove useful. I may specify one of these—*Cuesta* (Spanish for the flank or slope of a hill, but also used for a hill itself)—as the kind of a word which, in my opinion, is not demanded either by the necessities of an advancing science, or as representing a new idea. And if we see fit to name one kind of a hill *cuesta*, with just as much reason we may baptize with new technical names all the different parts, kinds, sizes and shapes of hills on the face of the earth, while students may be asked to fill their bellies with these husks of science under the impression that they are necessary parts of the science itself. Everyone remembers the story of Agassiz setting a new student to study a case of birds, and how, when he reported a few hours later that he knew all of their names, he was told to forget the names and to go back and study the birds.

But the main point is whether such things advance knowledge or serve important purposes in that advancement. When Mr. Gilbert described certain structural features of deep-seated igneous rocks he advanced our knowledge, and when he gave us a rational name by which to call those hitherto unknown forms he gave us a label for that knowledge. But it hardly follows from an instance of this kind that forms and structures that geologists have long known and comprehended should be given new names either from the Spanish or from any other language. We shall not understand a synclinal mountain any better by calling it a 'Shickshinny.' It is hardly a case of new bottles needed for new wine.

Terms that save men's time and nervous energy are helpful and welcome; those that consume time and energy without adequate return are 'useless incumbrances.' For this is a pretty busy world, and as many of us are anxious to keep pace with what is going on in geology and geography we often feel impelled to say to contributors, as we do to callers at the the office during business hours: "Be plain; be brief."

Local names serve good purposes with students who are obliged to get their ideas of geology from local illustrations, but such names should be kept at home; in the general literature of the subject they are what the European geologists call them.

One's feeling the need of a new term, or his having found one 'serviceable in his lectures during the past winter,' are certainly not of themselves sufficient reasons for introducing them to the public.

Technical names are a necessary evil, and new ones cannot be avoided; but it is our duty to increase this evil as little as we can, and only after duly weighing the pros and cons of each case. JOHN C. BRANNER.

STANFORD UNIVERSITY, CALIFORNIA,
July 12, 1897.

NOTES ON SOME FOSSILS OF THE COMANCHE SERIES.

THE description and figure of *Turritella leonensis* given by Conrad in the Report of the Mexican Boundary Survey implies that all of the whorls of the shell in that species are rounded. In my 'Description of Invertebrate Fossils from the Comanche series in Texas, Kansas and Indian Territory' (Colorado College Studies, V), I described *Turritella denisonensis* from the Choctaw limestone of northern Texas, noting its resemblance to *T. leonensis*, but separating it from that species on the ground of the much enlarged and angulated, or shouldered, body-whorl. In 1895 Mr. R. W. Goodell brought some fragmentary but interesting specimens of *leonensis* from the Trans-Pecos region of Texas, whence came Conrad's types of the species. One of these shows the body-whorl to be enlarged and shouldered as in *denisonensis*. I therefore suspect the latter to be a synonym of *leonensis*. As the northern specimens have been found in both the Choctaw and Grayson members of the Denison formation, while there is reason to believe that Mr. Goodell's specimens are from the Washita formation, it is probable that *Turritella leonensis* ranges throughout the entire Gainesville division.

In 1893, in the Fourth Annual Report of the Geological Survey of Texas (Part II., page 232), the writer noticed a shell that had been collected by Mr. L. S. Williams from 'drift,' in northern Texas, briefly characterizing it as a variety of *Turritella seriatim-granulata* and assigning to it the name *ventrivoluta*. Our first positive knowledge of the stratigraphic place of this shell is afforded by a fine specimen which the writer found in 1893 (only a few months after the original notice of the shell had been published) near Belvidere, Kansas, in the lower part of the Kiowa shales, viz., the Fullington beds, which correspond more or less nearly with the Kiamitia of Texas. The specimen is complete, and the half which is free from the matrix affords an apertural view of the shell in its entire length. The ornamentation is well preserved and, taken in connection with the other characters, shows that the shell is very distinct from *T. seriatim-granulata*. Like the latter species, it belongs to the subgenus *Mesalia*, and should be known as *Turritella* (*Mesalia*) *ventrivoluta*.

Turritella belviderei, sp. nov.—Shell of medium size in the genus, consisting of ten or more flattened or somewhat convex whorls; suture feebly impressed; aperture round-rhombic, slightly elevated; whorls ornamented with about six subequal to unequal, abruptly elevated revolving ribs whose summits are beaded, each bearing a rather closely-set series of oblique to transverse prominent granules; the intercostal intervals square-bottomed, those of the upper spire-whorls and of the lower parts of the body-whorl and first spire-whorl wider than the ribs, those of the upper parts of the body-whorl and first spire-whorl respectively less than and about equal to the ribs; upper rib and tubercles of each whorl usually coarser than the others, especially so in the case of the body-whorl, in which the large tubercles are sometimes distinctly arcuate (concave on the side away from

the aperture), an attenuated rib, or raised line, (sometimes two) developed just above it, about on the suture, the second rib above this being also sometimes smaller than the average.

Measurements.—Hight 45 to 60 mm.; breadth of body-whorl 17 to 20 mm.; divergence of spire-slopes (variable) commonly between 18 and 23 degrees.

Occurrence.—In the Kiowa formation at Belvidere, Kansas. It is the common Turritella of this formation, and is very abundant and well preserved in limestone bands in the Fullington horizon at that locality. Specimens preserved in the carbonaceous clay-shale parts of this horizon are usually found crushed.

This shell has hitherto been cited generally under the name, *Turritella seriatim-granulata*, but is distinct from that species as described and figured by Roemer.

I have elsewhere listed as '*T. marnochi*' and '*T. seriatim-granulata*, var. *marnochi*,' a large Turritella which is common in the Champion shell-bed at Belvidere. Recently, I submitted to Mr. T. W. Stanton, of the United States Geological Survey, specimens of the shell so listed. Most of these were returned without comment; but one, whose only differences from the others seem to fall within the individual variation of the species, was returned with the comment, "This specimen is more like Roemer's type of *seriatim-granulata* than any other I have seen, the chief difference being its larger size. Comparison was made with a squeeze from the original." Since all of these specimens agree in general character of ornamentation with *seriatim-granulata* as represented by Roemer in his Kreidebildungen von Texas, and since, at the same time, there is in many of them a tendency to that elongation of the granules which Dr. White represents for his *Turritella marnochi*, it seems altogether probable that the original *marnochi* and the large Turritella of the Champion shell-bed that I have hitherto referred to *marnochi* represent one and the same species, the *Turritella seriatim-granulata* of Roemer.

A careful study, recently made, convinces me that the common *Turritella* of the Kiowa shales, to which, in Bulletin No. 11 of the Washburn College Laboratory of Natural History, I applied the varietal name, *belviderei*, should be recognized as a species distinct from *seriatim-granulata*, and I have accordingly described it as such under the name thus early applied to it.

Omitting common points, the two species may be characterized for determinative purposes as follows:

T. seriatim-granulata. (Including *T. marnochi*, apparently as an individual variation.)

Size large; granules mostly well interspaced, coarse, appearing as small, low, rounded tubercles, or elongate with the trend of the revolving costellæ, both forms of granules often appearing on the same specimen and in variable proportion.

T. belviderei.

Size usually smaller; granules finer, prominent, numerous and crowded, their greatest diameter either transverse to costellæ or oblique.

So far as I am aware, there is no conclusive evidence of inter-gradation of the two types, though there is variation in both.

But here arises the question of the relation of *Turritella belviderei* to Meek's *T. kansasensis*, of the Mentor beds. The latter species, which attains a much larger size than is credited in the original account of it, is described as if ornamented with simple linear revolving ribs. As usually indicated by the mould, it is so ornamented; but in some instances there are traces of granules on the ribs, though only of feeble ones so far as yet observed. Aside from their summit-form, the ribs have the same characters as those of *T. belviderei*, viz., abrupt elevation, square-bottomed intervals, etc. The sinuous trend of the growth-lines in this species is found also in *belviderei* and *seriatim-granulata*. *T. kansasensis*, as now known, has the ribs plain or nearly so. But the moulds sometimes seem to be coated with a ferruginous film which may have obliterated distinct granules if such were originally present; and the query arises whether new and better material might not show strongly granulated ribs, and *belviderei* so become a specific or varietal synonym of *kansasensis*. At the same time, it is certain that in many Mentor fossils the moulds preserve the impress of the surface-sculpture in its finest details.

An apparent difference of ornamentation like that between *Turritella kansasensis* and *T. belvi-*

derei exists between the Mentor fossil, *Margarita mudgeana* Meek, and the Kiowa species, *M. marcouana* nobis; and here also it remains to be shown whether the difference is genuine or due to unlike conditions of preservation.

I have recently identified *Nerinea acus*, Roem., from the Champion shell-bed at Belvidere, the markings shown as in Roemer's figure of the type. This, with the *Lithophagus* noticed below, brings the total number of Invertebrata known from this thin but remarkable shell-bed up to thirty-eight. This interesting occurrence of *Nerinea acus* further confirms Professor Hill's earlier and my own constant later reference of the Champion shell-bed to the Fredericksburg formation, and to the Comanche Peak limestone in particular; and the occurrence of the *Lithophagus* in both the Champion and the Kiowa not only adds to the former evidence of a closely successional time-relation of the two formations, but also tends to emphasize the conclusion I have elsewhere announced, that the Kiowa is about equally related to Fredericksburg and Washita.

The *Lithophagus* referred to is one of which I found several specimens in burrows in Serpula-knots in the Champion shell-beds, and which is assumed not to differ specifically from the '*Lithophagus* sp. nov.' of Stanton, reported (in Hill's 'Outlying Areas of the Comanche Series in Kansas, Oklahoma and New Mexico;' Am. Journ. Sci. 3rd Series, Vol. L), as occurring in Gryphæa-valves in the Hill and Gould collections from the Kiowa shales at Belvidere, borings similar to those in the Serpula having been found by the writer in Gryphæa-valves at the zone of transition from the Black Hill shale to the Fullington bed, a horizon intermediate in position between the two which have yielded the actual shells of *Lithophagus*.

In 1893 I collected in the Comanche Peak limestone of south-central and north-central Texas several specimens of an apparently undescribed, heavy-ribbed species of *Cyprina*, to which I have given the manuscript-name *Cyprina laticostata*. I now recognize as belonging to this new species the cast which, in my 'Study of the Belvidere Beds,' I referred to *Homomya alta*, Roem. Thus the evidence for reference of the Champion shell-bed to the Comanche Peak limestone of the Fredericksburg division continually becomes clearer.

Stratigraphic Names for Caprina and Caprotina (or Requienia) Bearing Beds of Northern Texas. In defining the Barton Creek limestone, a member of the Fredericksburg formation (*American Geologist*, XVI., 385), I fell into the error of including in it both the Caprina limestone and the Caprotina limestone of Shumard, whereas it was the former only (whose fauna includes both *Caprina* and *Caprotina*, or *Requienia*, with other genera of *Chamidæ* and *Hippuritidæ*) that should have been included in the definition, and which was especially intended, this being the limestone that succeeds the Comanche Peak limestone, on Barton creek, in Travis county, Texas. It is the cap-rock of a number of buttes that carry remnants of the Fredericksburg formation in central and western Texas. The Caprotina limestone of Shumard is the Caprotina or Requienia bed that occurs in the upper Glen Rose, in the Brazos Valley, in the vicinity of Granbury, and which may be designated as the *Granbury bed*, to distinguish it from more or less similar beds elsewhere. Since proposing the name Barton Creek for the Caprina limestone of the creek thus named, I have observed that the name is quite similar to that of the Barton clays (Tertiary) of England. The similarity is the more unfortunate because increased by my inadvertently referring to the Texas bed in a shorter form, 'Barton,' in formally defining it, immediately after having defined it in table as 'Barton Creek.' Altogether, the considerations stated probably render either 'Barton' or 'Barton Creek' untenable, and both terms are therefore here abandoned in favor of another. The same bed of Caprina limestone that occurs on Barton creek may be seen overlying the Comanche Peak limestone, in Stonewall county, Texas (where, as Messrs. Dumble and Cummings have shown, and as the present writer has later observed, it forms the cap-rock of Double mountain); and the name *Stonewall limestone* is therefore here proposed for it.

OYSTERS: A REVIEW OF IGNORANCE.

ONE of the greatest services which science is doing for the world is the exposure of ignorance, and the inculcation of the doctrine that a thorough groundwork of the rudiments of general science should be laid by those who aspire to teach or to practice medicine, and it should be appreciated by the public that those alone who possess it are worthy of confidence.

In illustration of the actuality of the need, and partly as a review of the question concerned, I will criticise a leading article contained in a journal called *Modern Medicine and Bacteriological Review*, which purports to show that the oyster must be abandoned as a food.

This article begins by reciting the plenteousness of bacteria in the oyster, and says it is "a creature whose diet consists of the offal of the ocean, and which lives upon material so filthy and noxious in character that it requires the unceasing activity of a liver constituting nearly one-half the bulk of its body to protect it from impending death." It then cites the cases of typhoid fever traced to the oyster, quoting the *British Medical Journal*, which comments on the need for supervising the oyster beds; and then the editorial remarks that the beds are usually seated in the mouths of rivers and bays: "The oyster is fond of typhoid bacilli; it eats them as a tidbit; it will not miss a chance of swallowing millions of these mischief-making germs if opportunity is afforded. Indeed, this is the very business for which nature designed the oyster. It feasts upon the slime and ooze which covers the ocean's bed, near the shore, and the seaweeds which grow in such localities. The oyster has neither teeth nor claws with which to tear and masticate solid food. It is designed to live on the decomposing germ-infected substances which, with its filmy beard, it wipes off the slime-covered weeds and stones which abound in oyster beds."

The writer of this screed, posing as a bacteriologist and zoologist, seems to be ignorant alike of both sciences. We can here get an idea of the amount of harm which can be done by *soi disant* teachers through the medium of alleged scientific journals.

It is in the first place evident that this writer is ignorant of zoology. He does not know how the oyster feeds; he thinks it wipes its food off the weeds with its beard! I have seen some individuals use their beards for dinner napkins, but the oyster's is truly useful; it is fork and spoon, too, it appears! Every student of natural history should know that the oyster's beard or ctenidia is his gills; that he feeds by drawing a current of water by ciliary action mainly of the ctenidia into his mouth and lives on the solid particles which are contained in the water, and that the so-called liver is a digestive gland.

Furthermore, the oyster is plainly not designed by nature for a scavenger. His natural habitat is on a clean rocky bottom, and not in the mouth of a river, as fresh water is injurious to him, consequently he cannot live on slime and ooze. When oysters are 'parked' into a muddy or even a sandy bed they do not thrive at all.

After this display of biological ignorance one wonders if the writer, presumably a doctor, can tell a mollusc from a worm.

Now, as to the bacteriology of the matter, it is plain that if the oyster feeds on typhoid bacilli he must assimilate them, and when living things are digested they generally die during the process, consequently when we eat an oyster we do not eat live bacilli. But they can live in the stomach and gut a long time, also other enteric parasites.

It is an unquestionable fact that typhoid fever could not be caused by the introduction of any number, even millions, of dead bacilli into the human body, but, at the most, some temporary illness from the ptomaines in the mixture.

Finally, the 'Medical Progress and so forth' assumes that the oyster's large liver, which, as stated above, is not homologous to the liver, is a poison trap. I was not aware that this was the main function of an hepatic cell. Plainly, the primary deduction from a large liver would be that metabolic processes were complex and that nutriment needed to be stored in large quantity. The oyster's liver, however, does not seem much different from those of his congeners.

All this sensational essay of ignorance will doubtless be reproduced by the small-fry medical journals and the daily press. It must contribute toward hurting the oyster industry. It

must result in many invalids being deprived of a luscious and digestible food, and last, but not least, help to belittle science by reasoning which the common sense of centuries shows to be absurd.

Contrast all this with the calm attitude of the scientific *British Medical Journal*, which contents itself, according to the quotation from it, with calling for scientific investigation of the reason for some beds being polluted.* It seems quite likely that isolated oyster beds might be contaminated with bacilli, but the natural history of the oyster shows that he could not exist under such conditions, and that the bed would die out. In fact, the danger will apparently regulate itself.

I hope that these remarks will draw the attention of practical biologists, competent to set the question at rest; at the same time they will serve to show the great need of at least an elementary knowledge of science among our doctors before they presume to settle questions of the food supply of mankind; and they will serve to show the great lack of that knowledge among the rank and file of practitioners, who, at any rate, 'out west,' appear rather to glory in it.

GEORGE CHAS. BUCHANAN.

CEREBRAL LIGHT.

IN darkness or with closed eyes we can always see irregular forms of light in our visual field. These forms are of various kinds, series of waves, successive rings that spread and break, etc. In addition to these definite figures there is always more or less definite irregular illumination over the whole field. These phenomena are generally called the 'retinal light' or the '*Eigenlicht* of the retina.' They are usually supposed to arise from chemical changes going on in the retina. I wish to record some observations that apparently prove them to be cerebral and not retinal processes.

1. With closed eyes there is only one illuminated field, not two, as there should be from the two retinas if the light were retinal. Two retinal figures might appear as one under the conditions: (*a*) Of suppression of one field, which is not the case here, because it is impossible to keep one field suppressed for many minutes, whereas I have watched the retinal figures in uninterrupted continuance for a long time; (*b*) of perfect identity of form, which is hardly a possible supposition in the case of these irregular, volatile, chemical phenomena; (*c*) of sufficiently similar construction for union by stereoscopic vision, which also is not the case, as there is no relief effect in the picture.

2. The figures do not change in position when the eye is moved. They are localized in front and remain in the same place, even if the eyes are directed to one side. I find, however, that if the eyes are turned to a new position and kept there, the central figure (a spreading violet circle with a phosphorescent rim) will soon afterwards follow the movement; there is thus a tendency for this figure to occupy the spot of sharpest vision.

3. The figures do not change in location when the eyes are displaced. When the eyes are looking at some definite object, *e. g.*, this page, a pressure of the finger on one of them will cause the page apparently to move. This is true whether the other eye is open or closed. Likewise, if an after-image is obtained, it will move upon pressure of the eyeball. The pressure displaces the eyeball and changes the projection of the retinal picture. This displacement does not occur with 'retinal light.' I have repeatedly observed these figures and have manipulated the eyeballs; I have found that they are not in the slightest degree affected by the manipulations. In order to avoid all possibility of errors of observation, I have made the experiments in a series alternately with eyes open and eyes closed. With the eyes open I observed a dimly illuminated window; with them closed I saw the 'retinal' figures. The former always followed the displacements, the latter never.

These observations are, I believe, sufficient to establish the proposition (which I have not seen elsewhere) that the phenomena of vision usually known as 'retinal light' and 'retinal figures' are not originated in the retina, but in the brain. They should therefore be termed 'cerebral light' and 'cerebral figures.'

The following hypothesis seems also justified:

The cerebral light is located in those higher centers of the brain which are connected with visual memories and imaginations. While watching the cerebral figures I find that my visual memories or phantastic figures appear in the midst of the cerebral light and frequently cannot be distinguished from them. The close connection of these cerebral figures with the contents of dreams has been repeatedly noticed by Johannes Müller and a series of later observers. There is also the possibility that the hallucinatory visions produced by hashish, mescal and other drugs may be simply modifications of this cerebral light.

SCIENTIFIC LITERATURE.

Grundriss der Entwickelungsgeschichte des Menschen und der Säugethiere von Dr. Med. Oscar Schultze. Bearbeitet unter Zugrundelegung der 2. Auflage des Grundrisses der Entwickelungsgeschichte von A. Kölliker. Leipzig, Engelmann. 1897. 8vo. Pp. vii + 468.

Kölliker's well known manual has been so thoroughly reworked by Professor Schultze that it is essentially a new work. In Kölliker's volume the embryology of the chick furnished many of the descriptions and illustrations. Schultze has omitted the chick altogether, confining himself strictly to mammalian development, and has added a comprehensive though very condensed account of the fœtal membranes and placenta in the chief groups of mammals. Many new and admirable figures have been added, of which a considerable majority are original and taken from the author's own preparations.

It is exceedingly difficult to characterize Professor Schultze's text-book fairly, for it combines superior merits with conspicuous and singular defects. It is utterly inadequate as a presentation of contemporary embryology, for it systematically neglects the morphological, phylogenetic and mechanical aspects of embryology, and consequently reads almost like an old-fashioned descriptive anatomy. An embryological writer might be excused for avoiding phylogenetic and mechanical themes, but the neglect of morphological considerations makes full success in writing a text-book an impossibility. To illustrate these criticisms it suffices to examine the account of the nervous system; in the development of this the history of the neuro blasts and of the division of the medullary tube into dorsal and ventral zones are the fundamental facts morphologically, but our author barely describes the neuroblasts, does not figure them at all, and makes no allusion to the two zones, which should form the basis of the whole account, for without understanding these zones no student can master even the rudiments of our present knowledge of the brain and spinal cord. Again, the epidermis is equally maltreated, for the history of the epitrichium is incorrect, and no mention whatever is made of the fact that the nails are modifications of the stratum lucidum. Erroneous are also the accounts of the development of the glands in the stomach, which do *not* develop in the same way as those of the intestine; misleading is the history given of the supra-renals, for the so-called medulla of the organ in the human species is not derived from the sympathetic *Anlage*. There are mistakes in the illustrations: in Figs. 194 and 195 the 'Zwischenhirn' (Diencephalon) is correctly designated, but in Figs. 217 and 263 the same division of the brain is called 'Mittelhirn' (Mesencephalon); in Fig. 327 the left side of the heart is called '*rechte* Kammer' and the right side '*linke* Kammer,' while the great vein is labeled 'Sympathicus!' Of the index complaint must be made: one searches it in vain for Hirnblasen, Nerven, Thyroidea and other headings.

In spite of these criticisms, which indicate that the usefulness of the book is severely limited, the manual remains one of many merits and of great value. The author is felicitous in his combination of brevity and clearness, and in avoiding cumbrous accumulations of details. The faulty illustrations are exceptions; very good ones indeed are the rule, good both in selection and execution. In printing them the publishers have sustained their high reputation in this regard. The author has studied at first hand, and is thereby enabled to make his descriptions fresh, vivid and interesting, and if he had included in his point of view

the recognition of relative morphological values he would have prepared a work of signal utility. The student who uses the 'Grundriss' as his guide may acquire a fair knowledge of the empirical facts of embryology, but he will still have to learn the morphological interpretation of these facts and their relative importance. Meanwhile he will have profited by better, more available and more matter-of-fact descriptions of the anatomy of embryos than can be found in perhaps any other of the smaller text-books of embryology.

C. S. MINOT.

Das Süsswasserplankton, Methode und Resultate der quantitativen Untersuchung. Von DR. CARL APSTEIN, Kiel, Zool. Institut. Mit 113 Abbildungen. Kiel und Leipzig, Verlag von Lipsius & Tischer. 1896. 200 pp., 5 Tabellen.

To Dr. Apstein, of the school of planktologists at Kiel, is to be given the credit of applying the methods employed by Professor Hensen in his investigations in the Baltic and North seas, and on the '*National*' Expedition of 1889, to the quantitative investigation of the plankton of fresh water. His field of operations has been the lake region of Holstein. The book contains a full report of the results of the quantitative, and to some extent the qualitative, examination of more than 300 collections made in 15 different lakes during 1890–1895. A description is given of the apparatus, methods of collection, of determination of volume, and of enumeration of the constituent organisms or planktonts, if we adopt the term recently introduced by Schröter. There is, unfortunately, no adequate discussion of the margin of error which the methods involve. An annotated list of the important limnetic organisms is given with data on the seasonal distribution, abundance with dates of maximum and minimum occurrence and reproductive activity, with other facts of œcological import. Many of the forms are illustrated by reproductions from original microphotographs by the author. The microscope in the hands of the skillful operator reveals vastly more than the ordinary microphotograph records. For the purposes of scientific illustration of organisms of the plankton, and especially in such a book as this, it seems undesirable to substitute a method which rests upon the relative opacity of tissues simply, for one based upon the clear interpretation of the trained observer. One has only to contrast Dr. Apstein's best results in this line with the figures he reproduces from Hudson and Gosse, and Lauterborn, to appreciate the superiority of a carefully made drawing in conveying to the inquirer details of structure, and even such features as contour, proportion and natural position of parts. The book is not a manual of the limnetic fauna and flora, and the novice and casual student must still depend upon monographs and the widely scattered literature of the subject for aid in the determination of the planktonts. It is, however, an epitome of the subject, indispensable to every planktologist and a valuable aid to every student of fresh-water fauna.

Our author distinguishes active, passive and tycho-limnetic forms among the planktonts. With the latter he places *Difflugia*, whose presence in the open water is attributed to gas vacuoles, which cause it to rise from the bottom, its true habitat. *Difflugia* is a very abundant and important member of the plankton of our own great lakes, where it occurs in association with *Codonella*, *Dinobryon* and other typically limnetic forms. It also occurs in the Illinois river and its adjacent waters throughout a considerable part of the year, but in the open water and not upon the bottom. The conditions of the occurrence are such as to place it among the active members of the plankton rather than among those which owe their presence to the accidents of wind and current.

Following up the line of his earlier work, Apstein brings forward a long series of observations in proof of the equal horizontal distribution of the plankton in a body of water. In 80 catches the greatest departure from the mean was 22.8%, and the average departure but 5.52%. These hauls are distributed in short series of 2–5 parallel catches in various lakes, but the distance separating the successive collections is not given, and in no case has a lake been subjected to a larger number of examinations made upon the same day at frequent and regular distances throughout its whole extent. It seems

not improbable that such an examination would enlarge somewhat the variation in distribution as above given. Indeed, in another connection Apstein cites four catches made in Dobersdorfer See upon the same day, in which the variation from the mean is 100% or more, in three instances out of the four. This wide variation is, however, explained by our author as due to the presence of intervening sand bars in the lake. The results of counting individuals of various species in the plankton taken on the same day at different localities show a uniformity less marked than that indicated by the volumetric determination. There is no indication whatever of the presence in the plankton of 'swarms,' which Apstein defines as a local accumulation of animals of one species in one locality while the surrounding area is slightly, or not at all, peopled by it. This uniformity in the horizontal distribution is due to the similarity of the chemical constituents in the water, resulting in a uniform growth of the phyto-plankton and the zooplankton depending upon it. It is thus primarily a matter of food relations.

The vertical distribution of the plankton was determined by the subtraction process, and is subject to the error produced by the progressive clogging of the net. It seems very desirable that this problem be attacked by the pumping method. Apstein's results indicate the accumulation of the greater part of the plankton in the surface stratum of 0–2 meters, in which from 1½ to 60 times as much plankton is found (per cubic meter) as is present in a similar volume in the water below a depth of 2 meters. In this particular his results are in harmony with those of Reighard, Ward, and Birge upon our own lakes. Most organisms prefer the surface waters, only a few rotifers and *Entomostraca* actively seeking the deeper and colder strata. The vertical distribution of many forms, especially among the phyto-plankton, is closely linked with the life cycle. The maximum numbers occur in surface waters, and as these decrease and resting stages appear, they seek the deeper water, to increase again and rise to the surface as the maximum returns.

Apstein still maintains that plankton-rich and plankton-poor waters are characterized by the predominance of the *Chroöcococaceæ* and *Dinobryon* respectively. Reighard has shown that these criteria cannot be adopted for Lake St. Clair, and later work is making it still more evident that waters may be rich or poor in plankton quite irrespective of the conditions attending such diversity in the lakes of Holstein. The suggestion that plankton-rich waters are occasioned by the abundance of water-fowl is of questionable value, though local data may seem to support it.

Only those familiar with the routine of plankton investigation can appreciate the vast amount of work which Apstein's book represents, though his results will command the attention of everyone interested in the œcological side of biology. The science of fresh-water planktology is still in its infancy; its methods are as yet imperfect, and its problems are so intricate that years of continuous investigation in a number of localities will be required to establish broad generalizations. Dr. Apstein has been a pioneer in the field, and the great value of his work lies in its exploratory character and in his suggestive mapping out of the problems of planktology.

C. A. KOFOID.

UNIVERSITY OF ILLINOIS.

GEOLOGIC ATLAS OF THE UNITED STATES. FOLIO 25, LOUDON, TENNESSEE, 1896.

THE Loudon folio, recently published by the U. S. Geological Survey, represents that portion of the Appalachian province which is situated between the parallels 35° 30′ and 36° and the meridians 84° and 84° 30′. This area contains 968 square miles, divided between Blount, Monroe, Loudon, Knox, Roane and Morgan counties of Tennessee.

The folio consists of a topographic map, a geologic map, structure sections, stratigraphic sections, a map of the economic resources, and descriptive text. The author is Arthur Keith.

The text begins with a general description of the Appalachian province and points out the relations of this part to the others, with regard to its surface features. The local features of the drainage by the Tennessee river and its tributaries, Emory, Clinch, Tellico and Little Tennessee, follow next in description.

The various forms of the surface are pointed out, such as the Great Valley of Tennessee and the portions of the mountain district and the Cumberland Plateau, by which it is bounded, and the relation between these forms and the underlying rocks is made clear.

Under the heading 'Stratigraphy,' the geologic history of the Appalachian province is presented in outline, and the local rock groups are fully described in regard to composition, thickness, location, varieties and mode of deposition. The formations, thirty-three in number, range in age from Cambrian to Carboniferous, far the greater part being Cambrian and Silurian. The mountain district is chiefly underlain by the Ocoee series, whose age is doubtful. Rocks of Carboniferous and Devonian age occupy two small belts on either side of the Great Valley, and Silurian and Cambrian strata are repeated in narrow belts along the Great Valley. Limestones, shales and interbedded sandstones make up the Silurian and Cambrian strata; sandstones and shales, with coal seams and a limestone near the base, constitute the Carboniferous, and the Ocoee rocks are conglomerate, sandstone, slate and limestone.

The details of the strata are graphically represented in the columnar section. The different manner in which the formations decay is discussed, and the dependence of the residual soils and surface forms on the nature of the underlying rock. Great changes occur in the formations of this region, and the Knox dolomite is the only one which is uniform throughout. The direction of change was exactly reversed between Cambrian and Silurian time.

In the discussion of 'structure,' after a general statement of the broader features of the province, two methods are described in which the strata of this quadrangle were deformed. Of these the extreme Appalachian folding, accompanied by faulting and metamorphism, is by far the most prominent and is about equally developed throughout the quadrangle. Faults, especially, are most strikingly exhibited here. Deformation by vertical uplift also is exhibited, but only in comparison with broad surrounding areas. In this quadrangle the Great Valley is at its narrowest, on account of the extreme shortening in deformation. The structure sections illustrate the sharp folds and frequent faults into which the strata were forced.

Economic products of this region are coal, variegated marble, red hematite, building stone, lime, clays, timber and slate. The outcrops of the formations containing these are illustrated on the economic sheet, together with the locations of the mines and quarries. The iron ore and slate are of minor importance now; the coal district is a part of the great coal basin of Tennessee, on the same formations as the chief mining center of the State; and the marble belts are a part of the principal productive region for that stone. Various conditions affecting the value of these deposits are pointed out, and the associations and availability of the building materials and timbers are discussed.

FOLIO 27, MORRISTOWN, TENNESSEE, 1896.

The Morristown folio, also recently published, by the same author, deals with that portion of the Appalachian province which is situated between the parallels 36° and 36° 30′ and the meridians 83° and 83° 30′. This area contains 963 square miles, divided between the counties of Greene, Cocke, Jefferson, Hamblen, Grainger, Claiborne, Hancock and Hawkins, all in Tennessee.

Included in the folio are topographic, economic and geologic maps, structure and stratigraphic sections and five pages of descriptive text.

After a description of the broader features of the Appalachian province, the local geography is analyzed. The various types of surface features are pointed out and their relations to the underlying rocks are shown. Local facts, such as elevations and the drainage by the tributaries of the Tennessee River, the Nolichucky, French Broad, Holston and Clinch Rivers, are detailed.

Under the heading 'Stratigraphy' the geologic history of the Appalachians is presented in outline. This is followed by a detailed account of the local rock groups in regard to their location, composition, thickness, variations and mode of deposition. The soils and forms of surface produced by each formation are discussed with the formations. Twenty formations are distinguished in this quadrangle,

ranging from Cambrian to Carboniferous, far the greater portion being Cambrian and Silurian. The rocks of Carboniferous and Devonian age are found only in two narrow belts in the ridge district and are represented by only four formations. Over the rest of the area Cambrian and Silurian strata are about equally divided. A great variety of limestones, shales and sandstones compose the Cambrian and Silurian rocks, shales and sandstones the Devonian, while only limestone appears in the Carboniferous. Great changes take place in the Silurian strata, and limestones on the northwest are represented by shales and sandstones at the southeast. The general character of the formations is graphically represented in the columnar sections, one being drawn for each of the two chief geologic districts.

In the discussion of structure, after a general statement of the broader features of Appalachian structure, the two types of deformation shown in this region are described, and instances are pointed out in the structure sections. In the ridge district the most prominent feature is the faulting, which has cut the strata up into long, narrow blocks and produced the characteristic ridge topography. Southeast of Holston River the rocks were deformed by close folds. Deformation by vertical uplift is also existent in this region, but it can be observed only in comparison with other and larger areas. In the structure sections most of the details of the different structures are shown.

Economic products of this region are marble, building stone, lead, zinc, lime, cement, clays and timber. The outcrops of the formations containing these are represented on the economic sheet as far as possible, together with the locations of mines and quarries. The principal industries are the production of zinc and marble; the timbers and water-powers are also of general importance. The various conditions which affect the development of these resources are discussed.

SCIENTIFIC JOURNALS.

AMERICAN CHEMICAL JOURNAL, JULY, 1897.

On the Decomposition of Diazo Compounds: By W. E. CHAMBERLAIN, G. F. WEIDA and W. BROMWELL. The three papers contained in this number of the journal on this general subject give the results obtained in the study of the action of methyl alcohol on certain salts of diazobenzenes and diazotoluenes. Chamberlain, following up the suggestion of Remsen and Dashiell, found that, while under ordinary atmospheric pressure the main reaction between methyl alcohol and paradiazotoluene nitrate consisted in the substitution of the methoxyl for the diazo group, yet when the reaction took place under diminished pressure the hydrogen reaction was more favored. With an increase in the pressure the product remained as under ordinary pressure. When sodium methylate is used, and when an alkaline carbonate is added to the alcohol, only the hydrogen reaction takes place. Beeson found that alkalies and zinc dust would not only cause the formation of benzene, by the decomposition of a salt of diazobenzene, but also of diphenyl. The author of this work was, however, unable to obtain any ditolyl from an analogous decomposition of diazotoluene, probably owing to some different conditions of temperature at which the reactions take place.

Weida has compared the results of the decomposition of the three nitranilines and aminobenzoic acids with methyl alcohol, with the results obtained by Remsen and Graham when ordinary alcohol was used.

In the case of the orthonitrodiazobenzene sulphate the only product was nitrobenzene; but the meta- and para-compounds gave a small amount of nitranisol beside the nitrobenzene. The salts of the diazobenzoic acid did not act as they did when treated with ordinary alcohol, but showed a tendency to give the alkoxy reaction. They all gave as the principal product the ethereal salt of the corresponding methoxy acids.

Bromwell followed the same line of research as Chamberlain, using, however, the ortho-compound where the latter had used the para. He found that the ortho-compound decomposes at a lower temperature and gives the alkoxy reaction as the other does. When orthomethoxytoluene was treated with cold concentrated sulphuric acid a monobasic sulphonic acid containing one acid residue was formed, and when it was oxidized the corresponding benzoic

acid was formed. A number of the salts of the acid were prepared.

On the Action of Potassium Hydroxide on Orthomethoxysulphamine-benzoic Acid: By CHAS. WALKER. When the sulphonic acid described in the last paper was converted into an amide and fused with potassium hydroxide the product was not, as was expected, the corresponding dihydroxy-benzoic acid; but, as the author has shown, orthoxysulphaminebenzoic acid. The change can be represented thus:

$$C_6H_3\begin{cases}COOH\\OCH_3\\SO_2NH_2\end{cases}\ldots\ldots\ldots\ldots\ldots C_6H_3\begin{cases}COOH\\OH\\SO_2NH_2\end{cases}$$

Several salts of the acid were also made and studied.

A Simple and Efficient Boiling-Point Apparatus for Use with Low- and with High-Boiling Solvents: By H. C. JONES. The author has modified the apparatus devised by Hite by making it longer and replacing the inner tube by a platinum cylinder. By these changes he claims to have avoided the errors caused by the cold liquid returned by the condenser coming in contact with the thermometer, and also those due to radiation of heat from the bulb of the thermometer. He also replaces the outer vapor jacket, so generally used, by a cylinder of asbestos. A number of results are given which were obtained with both high and low boiling solvents.

Aluminum Alcoholates: By H. W. HILLYER. As was stated in a paper published some time ago, the authors found that when an anhydrous chloride was added to aluminum in alcohol a rapid deposition of the metal and an evolution of hydrogen took place. Dry hydrochloric acid gas or a solution in alcohol will cause a rapid evolution of gas when added to the aluminum in alcohol, and if the action is once started it will continue for some time even if no more acid is added. When the solution cools a crystalline compound, probably an addition product of the chloride and alcohol, separates out. When stannic chloride and hydrochloric acid gas are used it is very important that the materials should be completely dehydrated, as the presence of a small amount of water will stop the reaction. The results seem to show that it is necessary, in order to get a satisfactory action of aluminum on alcohol, that it should be anhydrous; that it should contain an anhydrous chloride with which it can form an addition-product; and, that the aluminum should be coupled with a more easily reducible metal.

Behavior of Chloral Hydrate with Ammonium Sulphide: By J. LESINSKY and C. GUNDLICH. The authors found that a mixture of chloral hydrate and ammonium sulphide will, after a longer or shorter time, depending upon the temperature, form a dark precipitate. They suggest it as a possible test for the purity of chloral hydrate and propose to study the reaction and the product.

A New and Rapid Method for the Quantitative Separation of Iron, Aluminium, Chromium, Manganese, Zinc, Nickel and Cobalt: By A. R. CUSHMAN. This method, which is more rapid than those generally used, has been found very satisfactory; but no details can be given in a review, as it is already in the most condensed form possible. The following reviews are also given: A Resumé of Progress in the Chemistry of the Carbohydrates during 1896; Traité élémentaire de mècanique chimique fondu sur la thermodynamique, P. Duhem; Elektro-Chemische Uebungsaufgaben, F. Oettel; Theorie und Praxis der Analytischen Electrolyse der Metalle, B. Neumann; Le four électrique, H. Moissan.

THE VEGETATION OF THE HOT SPRINGS OF YELLOWSTONE PARK.

MUCH of the beauty of the so-called 'formations' of Yellowstone National Park lies in the brilliant tints of the mineral deposits, wet from the streams of hot water that issue from the thermal springs and geysers.

Formation is a general term employed to designate any mineral matter deposited by the geysers and hot springs. The amount of formation in the Park is extraordinarily large, but it is chiefly confined to four regions. At Mammoth Hot Springs there is an immense deposit of calcium carbonate, the sides of which are terraced with pulpit-like projecting basins, as is shown in figure 1.*

These interesting basins are formed by the activities of numerous hot springs upon the top and along the sides of the terraces. The entire pile of dazzling white mineral has been likened to the front of a glacier. The Norris Geyser Basin, the Lower Geyser Basin and the Upper Geyser Basin are similar to one another in certain respects. They are extensive expanses of formation chiefly silicious in composition. All of them are situated in the floor of a valley and cover acres on either side of the Firehole River, which flows between banks of snowy whiteness. Upon these formations are scattered the numerous mounds built up by the geysers, and here also are many clear pools of hot water. The latter are of various sizes, some mere shallow puddles which sizzle and sputter, but most of them deep basins with sloping sides, and one at least a pond a hundred yards wide. The water is almost always scalding hot, sometimes even boiling violently in the middle of the pool.

*Figures 1, 5 and 7 are taken from the Ninth Annual Report of the United States Geological Survey.

Dry formation is generally dazzling white, as pure and clear as any snow field of the Alps or Norway. Dry formation reflects the light from innumerable crystals and the rays all seem to focus upon the individual in the proximity. This is why the formation is so hot and blistering. This is why the kodak must be 'stopped down' to its smallest diaphragm if one desires to photograph the geysers, as many a tourist has learned to his sorrow when he viewed the dark brown, over-exposed film of some geyser in action, and then remembered the long wait in the glittering sunshine, the mad rush for favorable points of view and the supreme satisfaction that he felt when the exposure was indexed and described: 'Old Faithful from the west, sunshine upon the vapor clouds, fir forest in the background.'

Wet formation is usually colored. Wherever a stream of water flows from a hot spring the course is marked by streaks of green and yellow along its margin. Fringes and rims of green and gamboge border the boiling pools. Upon the sides of the pulpit basins (see Fig. 1) are flutings of red and orange, of green and brown. The sides and bottoms of the streams are lined with olive colored felts of a velvet-like consistency, and there may be green or brown stringy filaments waving to and fro in the hot currents of water. The sides of many of the pools are covered with green, leathery membranes, or smeared with a coating of structureless jelly. Even the hottest pools, those which are boiling violently in certain parts, are likely to have some of the colored fibrous or gelatinous deposits at their edges. The temperature of the water in these streams and basins is frequently above 80° C., and water boils in Yellowstone Park in the neighborhood of 92° C.

Almost all of this brilliant coloring is associated with growths of low forms of plant life. Some of these organisms it will be our purpose to describe, together with a discussion of certain activities manifested by them in connection with the structure and development of the formation. It is not difficult to see that the growth is various in character in different parts of the hot springs. One finds the most luxuriant masses in such portions of the streams as have cooled down to a relatively low temperature, that is where the water, instead of being scalding hot, may be simply unbearably warm.

Here, at a temperature of from 40°–50° C., flourish a variety of forms with the greatest display of color. The prevailing tints are green, but much of the growth is brown, red or frequently orange. The forms which the masses of vegetation assume depend upon the condition of the environment. If there is a rapid stream the bottom will be covered by a smooth, slippery, leathery felt, and perhaps occasional stringy masses attached at points along the sides and bottom will float out with the current. If water lies in a quiet pool one may find a thick growth of this felt-like character on the bottom and there will be numerous tufts perched upon projecting knobs of rocks. These tufts are made especially prominent by the bubbles of gas entangled in the network of filaments. The tufts are particularly interesting because they give rise to some of the most peculiar sculpturing of the shallow pools.

In warm water, at a temperature of from 55°–65° C. there is a preponderance of green growth, much of it a vivid emerald green. The color becomes less pronounced in warmer portions of the stream, fading to a yellowish brown, and finally becoming light yellow when the water approaches 80° C. in temperature. In the hottest water one finds only white filaments, which grow as long silky strings in the running streams or form a delicate cobweb upon the bottoms of quiet pools. This is the growth that marks

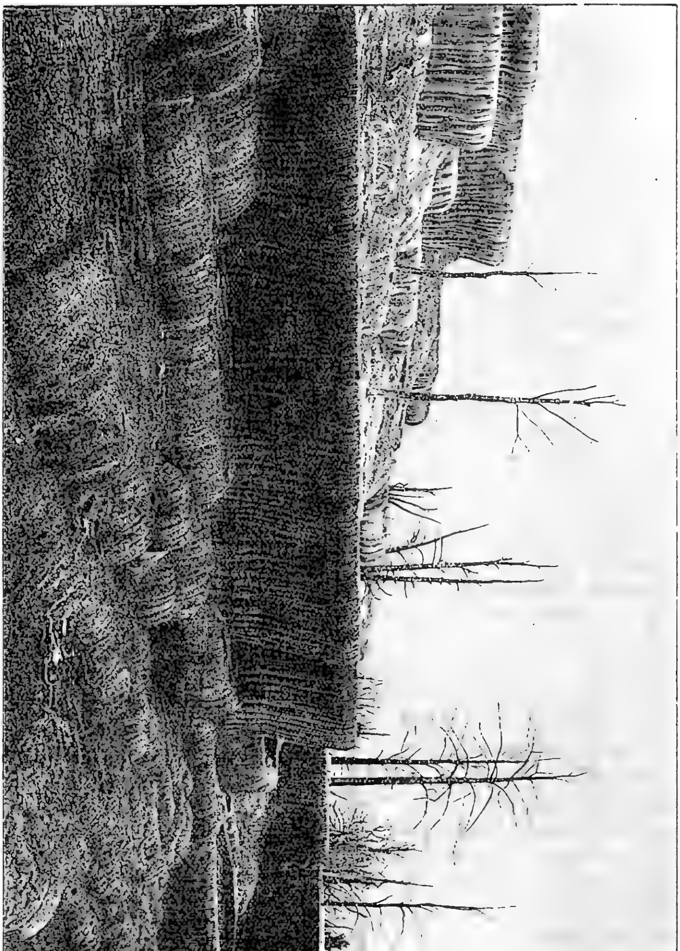

FIG. 1.—Pulpit Basins. Mammoth Hot Springs.

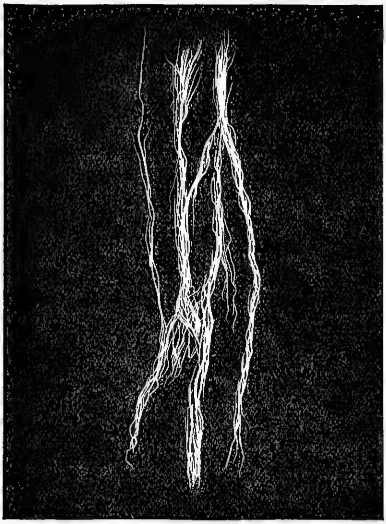

Fig. 2.

the limit of life in these hot springs, and it is not likely to be found in water warmer than 85° C.

Let us now consider the structure of some of the most striking types of plant life making up the vegetation of these hot springs. It would not be wise to go into details, and indeed I cannot well do so, for no one has ever published a critical study of these forms. The subject is really a very difficult one for several reasons. In the first place the organisms are all very minute and can only be studied under the highest powers of the microscope. The characters which define the species are particularly evasive because the forms are extremely simple in structure, and color and size are notoriously variable qualities among such organisms. Then these forms must be carefully compared with the inhabitants of other hot springs, particularly those of Germany and Italy, where such growths have been somewhat extensively studied. This is necessary in order to place the identifications upon a firm basis.

Naturally, the most interesting forms from our point of view are those living in the hottest pools. The growth is usually white or gray; much of it has a pearly luster, and the structure is filamentous. In quiet water it forms a delicate network on the bottom. In the little streams which carry off the overflow from boiling pools one may find the filaments in tufts along the edge. Such tufts often appear as in Fig. 2, but the filaments may grow to be six inches long. The highest temperature of the water in which this growth has been so far reported is 85° C., life conditions which must, indeed, be considered remarkable.

Examined under the microscope, the filaments present some curious features. Under the low powers one sees an apparently homogeneous strand of a gelatinous consistency, shown in Fig. 3, that is coated

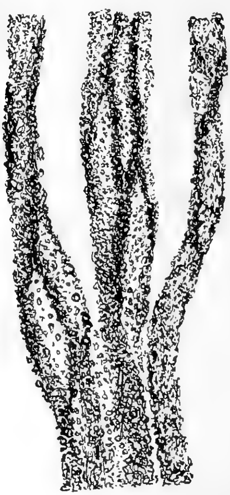

Fig. 3.

all over with small crystals. It is easy to prove that this deposit is sulphur, since the granules can be dissolved away in carbon bi-sulphide, leaving only the gelatinous filament quite soft and flaccid, where it was formerly somewhat stiff and stringy. One sees no further indication of organization until the filament is examined under an immersion lens with, perhaps, a magnification of 1,000 diameters. Even then, to obtain the best results, the specimens must be stained. Such preparations then reveal a remarkable structure. The filament is made up of innumerable bacteria imbedded in a gelatinous matrix. They are chiefly rod-like forms and are arranged in lines and chains. The individual rods vary greatly in length, but it is quite plain that the smaller forms result from the division of the larger. Fig. 4–a illustrates the characteristic form and arrangement of these bacteria under very high magnification, about 2,000 diameters. The long axis of the rods are usually parallel with the general direction of the filament, the width of which is made up of many hundreds of the organisms placed side by side. The filament is really an elongated zoogloea, or colony of bacteria, all coated over with sulphur grains.

It is a difficult matter to determine exactly what form of the bacteria this is. One should know whether the sulphur grains are deposited by the activity of the organism or not. Presumably this is so, and the type is a species of *Beggiatoa*, a genus of bacteria characterized by its peculiar habit of depositing sulphur from water containing sulphuretted hydrogen in solution. But the genus *Beggiatoa* is remarkable because it includes some of the largest species of bacteria known, and the cells are of such a size that many sulphur grains may be contained in their interior. There are without question species of *Beggiatoa* in the hot springs of the Park, and it may be just as well to compare one of these forms shown in Fig. 4–b, under magnification of 500 diameters, with the organism under consideration. It will be seen that the cells of the *Beggiatoa* filament are very large in comparison with those of Fig. 4–a, although the magnification of the latter is about 2,000 diameters. The dark dots in the interior

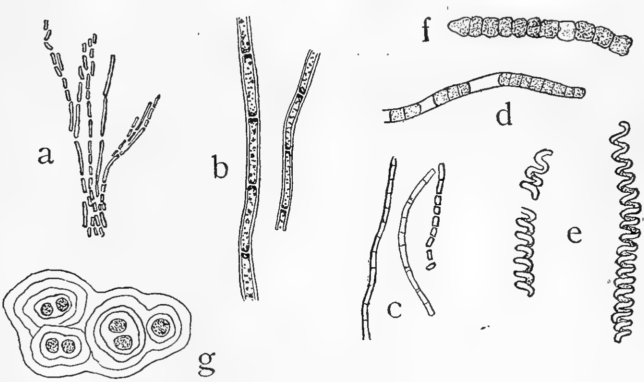

Fig. 4.

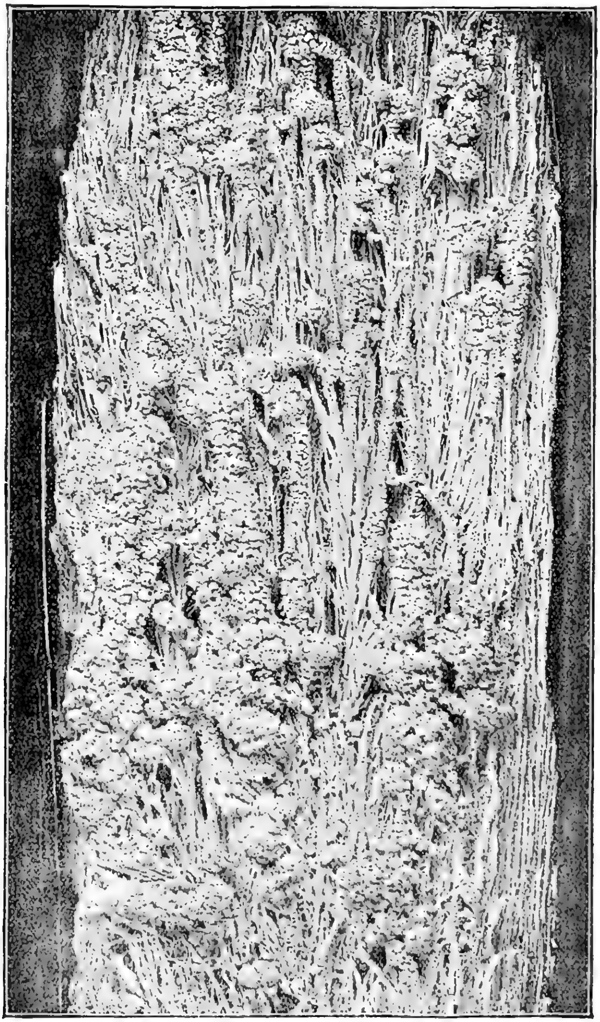

FIG. 5.—A Piece of Travertine.

of the cells are sulphur granules. If our plant is not *Beggiatoa* it would be classified as a *Bacillus* because of the rod-like character of the cells. The writer will not attempt to name it on the insufficient data, and it serves as an excellent illustration of the difficulties with which one contends in attempting to define precisely the relations of these organisms to one another. It is a very interesting form from its habits and its habitat, and probably the most adventurous organism in the hot springs.

This peculiar species of the bacteria leaves a record of itself in the mineral deposits in the following manner. The filaments, at first delicate and exceedingly flexible, become coated with such a thick deposit of sulphur and calcium carbonate that they lie as stiff fibers along the edges of the hot pools and upon the bottom of the streams. Sometimes the collections of these filaments have the appearance of frost work in the scalding hot water. Eventually the threads become cemented together by the continual deposition of lime, but they impress their individuality upon the resulting formation by giving it a fibrous structure. These points are well illustrated by the photograph of a piece of formation shown in Fig. 5.

The tufts of waxy bacterial filaments are often associated with extensive growths of quite a different character. Large areas upon the sides and bottoms of the pools and streams are frequently covered by a closely packed felt of extremely delicate filaments. The surface is smooth and slippery, and it feels like a sheet of rather stiff jelly all gritty because of the numerous crystals of calcium carbonate deposited in the substance. Under magnification the true structure is made apparent, and one sees here a closely woven mass of very minute filaments agglutinated together. The individual filaments are sometimes less than one-thousandth of a millimeter in diameter, so that they look like mere lines even under a magnification of 200 to 300 diameters. Fig. 6 illustrates the general appearance of

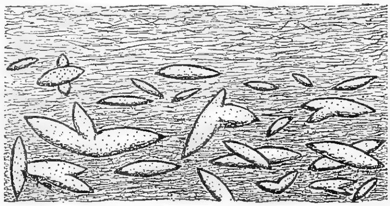

FIG. 6.

the leathery felt and shows the many crystals of calcium carbonate imbedded in the mass of filaments. The cells of this plant are several times longer than broad and the color is greenish. The genus is called *Phormidium* and contains forms closely related to a very common blue-green alga of stagnant waters, named *Oscillatoria*. There are several species of *Phormidium* in the hot springs, differing from one another chiefly in the measurement of the cells. The smallest forms, such as are shown in Fig. 4–c, are found in water as hot as 75° C., while the larger types (Fig. 4–d) only inhabit water that is several degrees cooler. The color of the *Phormidium* growths is quite variable. When actively vegetative the tint is bright green, but older sheets become brownish and the presence of various mineral deposits give the growths shades of golden yellow and dark red. If dried in the sun the colors fade out through various tints of yellow and pink to the everlasting white of the formation.

Another interesting plant frequently makes itself prominent, side by side, with the *Phormidium*. It is called *Spirulina* and, as the name suggests and the figures (Fig. 4–e) show, the form is a filament closely coiled in a spiral. This organism has the power of forward movement, the free ends swinging from side to side in such a man-

ner that the delicate thread travels over its substratum and among other algæ. *Spirulina* mixed with *Phormidium* often forms curious raised rims about the pools of hot water. This phenomenon is especially well shown upon the edge of the Prismatic Spring in the Middle Geyser Basin, also known under the more picturesque name of Hell's Half Acre. The Prismatic Spring is an immense pool of hot water about a hundred yards wide. The center of the spring is of a dark blue color, which gradually changes through shades of green to a light yellow around the margin, where the water is shallow over the sloping bottom of the basin. On the edge of the pool is a greenish growth variegated with brown and yellow. It has the form of a rim several inches wide raised above the mineral substratum and acting as a slight obstruction to the ripples of hot water that constantly splash over it upon the formation. The substance of the growth is rather firm like wet felt, and the surface, figured with raised lines, resembles tripe. The masses of wet algæ are so warm that one cannot hold them, and the water that laps the edges of the deposit is much too hot to approach with safety. It is in situations such as these that the algæ of thermal springs play an important part in moulding the form of the mineral deposits, but this is a subject that will engage our attention later on in the paper.

We have now considered the organisms that are most characteristic of the hot water of the thermal springs. It is altogether probable that careful studies on the spot would bring out many interesting facts in respect to the number of species, and the precise range of their distribution through the various springs in relation to the temperature and character of the water. It is an interesting field for study, and deserves the attention of a botanist for three months, instead of three days, which the writer once spent in the Geyser Basin.

As the water grows cooler in the overflow streams the conditions gradually become suitable for types more familiar to the botanist. A species of *Anabæna* (Fig. 4–f) is prominent in some places, and members of the Chlorophyceæ and diatoms are found, but these types are not truly a part of the flora of the thermal springs.

One more form deserves notice from the peculiarity of its structure and the curious situations in which it is found. There are places in the Geyser Basins and on the deposits of Mammoth Hot Springs where steam issues from the cracks and crevices of the formation. One may frequently find the mineral matter in these openings colored a bright green by a delicate film of slime. This is largely made up of *Glœocapsa* (Fig. 4–g), a unicellular alga that is characterized by the presence of very thick cell walls made up of concentric layers, the outer becoming gelatinous. These slimy films must be kept continually damp by the hot steam that issues from the vents.

The inhabitants of the thermal springs are all members of one or two families of plants, and a greater interest attaches to them because the fact is plain that the conditions under which they live are not suitable for the forms of algæ that commonly crowd our ponds and streams. In a general way they are all closely related to one another. The colored forms are all members of the class Cyanophyceæ, the lowest group of the algæ, and the colorless type all belong to the class Schizomycetes, or bacteria, the lowest group of the fungi. Moreover, the forms of Cyanophyceæ and Schizomycetes are quite generally considered to be near relatives. Indeed, all the members of both groups have been classified under one name by some authors and called Schizophytes, which means plants that split. All the forms agree in having a very simple

cell structure. Until quite recently investigators have been unable to find any indication of that organization of the protoplasm into a nucleus and chromatophore, such as is present in the ordinary plant cell. Now botanists are able to distinguish nuclear matter in the cells of some of the larger types, but it is found in a scattered form with vague contours and never in the shape of a well-defined, compact structure. The phenomenon of cell division is here found in its simplest type and gives the name to this group of plants. The cell simply splits apart and there are two individuals where formerly there was one. The cells may remain attached to one another and so form filaments of considerable length, but each cell is probably physiologically quite independent of its neighbors. The facts plainly indicate that the protoplasm of these types is not as highly organized as that of more complex forms of plants; probably they are able to withstand these unusually high temperatures because of this low grade of protoplasmic organization. Perhaps, but this does not necessarily follow, these organisms resemble more closely the primitive first forms of life than any other living types. One would like to know about the precise conditions governing the lives of these simple cells and something of their past history. It is possible that they may have crept into the hot springs from the colder water, or perhaps their ancestors may have always lived under the infernal conditions which now surround them. A very thorough study of various pools and streams at different temperatures might solve the problem. The field of study is as interesting as it is difficult.

Now let us examine these organisms in their rôle as geological agents or factors influencing the deposition and shape of the formation. We must remember that the formations are of two sorts: first, the calcium carbonate deposits illustrated most strikingly by the immense pile at Mammoth Hot Springs; and second, the silicious formations of the geyser basins. Calcium carbonate ($CaCO_3$), the substance which makes up the chief part of all limestone and marble, of coral and most shells, is practically insoluble in pure water. However, water charged with carbon dioxide (CO_2) dissolves calcium carbonate, and it is pretty generally believed that the latter passes over to a new substance, calcium bi-carbonate with the formula $Ca\,(HCO_3)_2$. But calcium bi-carbonate is not known in a solid crystalline form because, when water containing it in solution is allowed to stand exposed, the carbon dioxide escapes and the usual calcium carbonate immediately separates out from the solution.

The water that issues from the formation on the terraces of Mammoth Hot Springs has been under pressure and is highly charged with carbon di-oxide. It holds an unusually large amount of calcium carbonate in solution, a fact for which the bed of Mesozoic limestone, through which the boiling hot water passes on its way to the surface, is responsible. When the water emerges from the orifices of the hot springs and spreads out in the shallow streams and pools there is an immediate escape of carbon di-oxide from the supersaturated solution. The insoluble calcium carbonate is then thrown down as the dazzling white deposits of travertine. One may see the results of this property of the hot water illustrated by the absurd incrusted baskets, pine cones and horseshoes that are on sale at the hotels. This phenomenon is, of course, in no way connected with the activity of the organisms, and there is no question but that travertine would form and terraces would be built up even if no plant life were present in the water.

But the plant life undoubtedly hastens the deposition of calcium carbonate in the

following manner. The green plants require carbon di-oxide for the processes of assimilation and they take it from the water, which means, in this case, the deposition of a certain amount of calcium carbonate. There are many plants that have the power of taking calcium carbonate from water. *Chara*, the stone-wort, the marine algæ called Corallines, forms of the group Siphoneæ inhabiting the coral sands of Burmuda and Florida, are examples, and besides these there are species of Cyanophyceæ closely related to the forms actually found in these hot springs. If the tufts and felts be teased out, one may find innumerable crystals of calcium carbonate, varying in size, held in the meshes of the filaments. We have tried to show the appearance of such a preparation in Fig. 6. One may observe this very significant fact that the crystals at the bottoms of the tufts and sheets of algæ are large, and there are places where they have become cemented together into flakes of mineral deposits. In the middle region and towards the surface of the felts the crystals are small and scattered. It is evident that these expanses of algal growth lay down sheets of calcium carbonate and that the tufts build up little mounds upon the generally smooth surface.

It is altogether probable that the mineral deposits follow the development of the algæ very closely and actually entomb the older filaments at the bottom of the growths in limestone crypts. It is interesting to know that the first travertine thrown down in these waters is probably associated with the vegetation at the time of the deposit. We say probably because the fact cannot be proved in these hot springs, but we can reason from analogy, for the conditions here are quite similar to those of the waters of Carlsbad, in Germany. There the springs issue from granite rocks and the travertine is not deposited until traces of vegetation appear in the water. These interesting observations were made by Ferdinand Cohn. As all the streams of Mammoth Hot Springs issue from travertine deposits, it is impossible to tell exactly where the deposition first begins.

However important these algæ may be in their rôle as rock-formers, a greater interest attaches to them because most of the beautiful sculpturing and coloring of Mammoth Hot Springs is directly due to their presence. The rims on the pulpit basins (see Fig. 7) are covered with a growth of algæ. The interiors of the basins are lined with sheets of green and yellow on a white background, but it is the outside of the basins that exhibits the most beauty. There are pillars and flutings and stalactite-like structures all colored brown and orange and green. The algæ are responsible for almost all these peculiarities. If they were not present the water would flow in shallow sheets and fresh deposits of calcium carbonate would be laid down like so many coats of whitewash with unrelieved monotony.

But the algæ change the conditions. Here they grow in ropey welts down the sides of the pulpits from the lips of the basins; there they have formed a raised rim upon some flat surface and partially dam up some small pool or stream of water. Here they hang down from some projecting ridge as a slight fringe that drips water. Everywhere the growth of vegetation is but a thin veneer over a skeleton of mineral deposits that follows closely the lines of the algal sheet. The filaments project from a granular and gritty deposit enveloping the fibers that are not so fortunate as to be at the immediate surface. Consequently when, for some reason, the water ceases to flow over a certain part of the formation, and the colored vegetation dries up and entirely fades out in the fierce glare

of the sun, there is still left the form of the growth in raised relief upon the travertine.

In the shallow pools, only a few inches deep, one may find the most delicate frost-work creeping in from the side. Here the algal network is a skeleton upon which is laid a coating of calcium carbonate in the form of delicate granules. The filaments frequently have a beaded appearance, somewhat similar to cobwebs covered with minute drops of dew. The effects are particularly striking when a stream of water suddenly spreads out over a flat surface. Then the frosted growths radiate out from a common point and the effect is sufficiently prominent to give rise to the term 'fan' that is applied to such figures. Of course, the more delicate patterns upon the formation are not lasting. The wear and tear of the summer tourist season, and the freeze-up in the winter, break the lace work, but it is quickly renewed every spring. Indeed, there is opportunity for the exhibition of taste in the judicious distribution of the hot streams over the older portions of the formation. They could readily be kept in repair, for fresh deposits are laid down with astonishing rapidity.

We now pass to the consideration of the silicious formations of the geyser basin and here we encounter some peculiar problems. The water comes forth boiling hot and supersaturated with silicious matter. There is no question but what some of this must be thrown down from the solution as the water cools. Indeed, one may sometimes find soft deposits of a gelatinous nature around the vents of various springs and geysers, apparently thrown out by a sudden discharge. Evaporation alone would make possible the gradual building-up of the interesting cones around the orifices of geysers. However, the deposition as a rule must go on very slowly, and the calculation has been made that in certain instances not more than one-sixteenth of an inch is deposited each year.

But our problems are concerned with the beautiful transparent pools scattered over the formation. Their water is as clear as crystal and the mineral matter on the sloping sides is as firm and hard as chalcedony. There is no vegetation in the hottest of these pools, but where the water has cooled down a few degrees one may find abundant growths of algæ. There are membranous patches of various shades of green and masses of yellowish jelly and also tufts of very delicate filaments that hold many bubbles of gas entangled in their meshes, making them rise up like small balloons held down by numerous cords. There are many peculiarities about these pools that make them very interesting. The sides are frequently moulded into curious figures, giving reasons for such names as 'The Oak-leaf Spring,' 'The Aquarium,' etc.

But the most peculiar structures are pillars that stand up from the bottom of the basin. They are of various sizes, some merely slight cones that roughen the stony floor of the pools, others finger-like projections. In its fully developed state the column rises to the surface of the water. As it grows older it becomes gradually thicker until the mass of deposit resembles a small island in a miniature sea of hot water. Fig. 7 shows one of these shallow pools from which the water had been drained. There are many columns, large and small, present in this instance, and the figure illustrates a characteristic peculiarity, namely: that often the top of a pillar spreads out at the surface of the water in a form that resembles the umbrella-like top of a toadstool.

How are these columns and the figures in raised relief formed? Have they any connection with the algal vegetation? Indirectly there is a very important relation. It is not probable that these algæ secrete

silica. There are comparatively few plants that have this power and among the algæ the forms called diatoms are the only examples. They are not found in these hot pools. The writer has never heard that any member of the Cyanophyceæ has this power, and the specimens that he has examined from the hot springs gave no evidence that silicious matter was secreted directly around the fibers, for the deposits were in the form of granules of amorphous silica distributed among the filaments. It is a principle well known to the physicist that matter in solution is often far more likely to be thrown down when foreign bodies are in the fluid. The mere presence of such material offers surface or otherwise disturbs the equilibrium and hastens the appropriate physical changes. Thus the phenomenon of crystallization will take place much more quickly and completely from a solution if there be strings or other

FIG. 7.

bodies present upon which the crystals may form.

It seems probable that in these facts we have an explanation of the influence which vegetation appears to have upon the deposit of silicious material in the pools of the geyser basins. The mere presence of the algal filaments as foreign bodies encourages the deposition of silica, and it naturally follows that the greatest amount of silica is thrown down where the vegetation is thickest. This gives us the entire secret of the peculiarities of columns and mouldings. As has been before described, it is the habit of algæ in quiet water to grow up in tufts. A tuft once established leads to the deposition of more silica at that particular spot, and soon there will be formed a little mound or cone, capped and covered by a mass of filament. The algal filaments always tend to grow upward in quiet water, if for no other reason because of the numerous bubbles of oxygen thrown off, which, becoming entangled in the threads, tend to buoy them up. As the algal cap on top of a cone grows upward, more silica is laid down at its base, and so a column of deposit gradually rises. When the cap of vegetation reaches the surface of the water, there is, after the habit of such forms, an immediate radiation of the filaments in all directions. Consequently, when the final deposit of silica is left upon the top of the column, it extends on all sides as an overhanging capital. As the shaft of the pillar is covered with the sheet of vegetation, we can readily understand why it should thicken and why there might be irregular protuberances or even smaller columns rising at different levels along the sides of the larger. Of course, the algal growth will not be uniform on all sides of the pillars, any spot that is especially vigorous leaving a record for itself through a larger amount of mineral deposit.

Much more must be known about the exact conditions of growth in these thermal waters, before the many peculiarities of the mineral deposits are explained. But a new interest is added to the hot springs of Yellowstone Park and their deposits when one thinks of the parts these simple organisms play in the construction.

Children of steam and scalded rock, a story you have to tell,
Writ in the glare of sunshine bright,
Sculptured and etched in marble white,
Illuminated in colors bold,
Richer than ever parchment old,
Children of steam and scalded rock, what is the story you have to tell?

Our legends are old, of greater age than the mountains round about.
We have kept our secrets epochs long,
They are not to be read by the passing throng.
It is nothing to us what men may say.
If they wish our story the price they must pay
In hard brain work, ere the tales are told. We challenge mankind to draw them out.

Children of steam and scalded rock, your challenge must rest for the present age.
I have scarcely broken the outer crust
That covers the greater truth, but I trust
Some man will follow and therein find
Knowledge, that to the Present shall bind
The Past with cords wherein entwine
Threads of the perfect truth, divine.
Children of steam and scalded rock, some man to come will accept thy gage.

BRADLEY MOORE DAVIS.
UNIVERSITY OF CHICAGO.

RAREFIED AND CONDENSED AIR.

AFTER reading Paul Guessfeldt's enthusiastic description of 'mountain-ecstasy,' as he calls it, which the rarefied air of high altitudes produces and which he describes as consisting of 'an increased sense of joy caused by an increased muscular activity, and a wonderful buoyancy of the feelings which at moments rises to ecstasy,' we are tempted to follow him to those heights in order to experience these feelings which can be so easily obtained with a little physical exertion.

A different point of view is presented to us by D'Orbigny (1826) in an account of the sensations he experienced while crossing the highest pass of the Cordillera in Bolivia, which is 4,500 meters (about 15,600 ft.) high, on his way from the coast of Peru to La Paz. For several days before reaching the highest part respiration was difficult. His driver, the mule he was riding and his dog suffered so much that they were compelled to halt every 20 or 30 meters to regain their breath. While crossing the crest of the ridge he suffered intensely from pains in the temples, vertigo, and extreme difficulty in breathing. Every movement of the body produced palpitation of the heart, followed by a feeling of general debility, until bleeding of the nose finally relieved him. During this attack of 'mountain-sickness' he saw two natives, who had overtaken him, hurry on their way, climbing the rocks with the greatest ease.

It is evident that D'Orbigny did not belong to an Alpine club, and did not have the necessary training, or else he would not have suffered so intensely at an altitude which has no effect upon those who now ascend Mount Blanc.

A man who has had no practice in mountain climbing is apt to experience sensations similar to those which D'Orbigny described, while yet under the ordinary atmospheric pressure. For instance, in hurrying up a steep incline, say in the winter, when you sink into the snow with every step, you will very likely become short of breath, since the rapid climb prevents the full expansion of the lungs. This disturbs the circulation of the blood, which, being no longer freely admitted into the contracted lungs, collects in the veins. They swell up, the face becomes purple, the pulse-beats are accelerated, and palpitation of the heart sets in. In case the exertion is continued, an attack of nausea is imminent, together with a feeling of faintness in the lower limbs, as the overworked muscles are deprived of their requisite supply of oxygen. A few long drawn breaths usually suffice to remedy the disorder. By gradually becoming accustomed to walking and breathing slowly and regularly a further attack is prevented.

These symptoms, as they manifest themselves in the rarefied air of high altitudes, constitute what is known as mountain-sickness, and persons unaccustomed to mountain-climbing are frequently affected by it even while resting or when not exerting themselves. Here, again, the cause of the disorder is the insufficient expansion of the lungs, caused by the diminished atmospheric pressure which renders respiration difficult.

But, it may be objected that the energy with which we inhale the air is the same at high altitudes as below, and the rarefied air ought to penetrate into the lungs more easily. This is perhaps true, but, although we expand the chest during inhalation, the expansion of the lungs is only accomplished by means of the atmospheric pressure. The lungs are not attached to the inner surfaces of the thorax and can move freely. A wound in the thorax which admits the passage of air causes the lungs to contract, and all the exertions of the breathing apparatus will be powerless toward relieving this contraction.

As long, however, as the cavity of the chest remains closed and contains no air, the pressure of the air in the lungs acts from within outwardly and by expanding the lungs will cause them to remain in contact with the sides of the chest as it expands during the process of inhalation. The ease with which the lungs are expanded depends upon the amount of atmospheric pressure which is brought to bear upon their elastic power of resistance, and this action consequently becomes more difficult as the lighter pressure of higher altitudes is reached. Let

us suppose that the usual pressure is reduced to one-half, then the rapidity with which the lungs are expanded, although still greater than the usual rate of the chest expansion, is yet only half as rapid as when under the customary atmospheric pressure, and under certain circumstances this may seriously disturb inhalation.

Exhalation, on the contrary, is accelerated by the lighter pressure of a rarefied atmosphere. It generally takes place without the aid of the muscles which assist in the process of inhalation. The expanded parts, as the lungs, diaphragm, etc., contract to their original size and position by reason of their elasticity, as soon as the muscular force which was applied during inhalation is relaxed. The employment of the abdominal and intercostal muscles as an aid to exhalation is exceptional.

The only obstacle which retards the contraction of the lungs is the pressure of the outer air, which resists the outflow of the air from the windpipe and is diminished as the atmosphere becomes rarefied. Consequently the contraction of the lungs is greater and more rapid in a rarefied atmosphere. Exhalation is, therefore, in general, a mechanical process, and as such is subject to a certain law acording to which it can be performed on the summit of Mount Blanc in $\frac{8}{10}$ of the time required under the ordinary atmospheric pressure.

Humboldt tells us that newcomers in the vicinity of Quito, Ecuador, where the altitude is between 2,600 and 3,600 meters (11,800 ft.), have considerable difficulty in breathing, especially when talking rapidly. This is explained by the fact that the supply of breath usually reserved for the formation of sound escapes more rapidly and is therefore sooner expended. It has also been observed that some persons are unable to whistle where the pressure has only been diminished from 760 mm. (ordinary atmospheric pressure) to 500 mm. The whistling sound is produced by placing the lips in a certain position, and depends upon the rapidity with which the air is forced out of the lungs by means of the abdominal muscles. Naturally, the amount of muscular force so expended is still suited to the requirements of the denser air to which one has been accustomed. As the atmospheric pressure is diminished, the air escapes more rapidly and the expected sound is not formed. In order to learn again how to whistle, it is necessary to place the lips in another position and to apply the muscular force differently, which always requires considerable time and practice.

Physicians who have made a short stay at Davos, which lies at an altitude of only 1,600 meters (5,200 feet), state that during that time their respiration was much accelerated, while there was an inability to breathe deeply. The explanation of this phenomenon is the diminished atmospheric pressure which also causes an acceleration of the pulse-beats—the inevitable result of insufficient lung-expansion. Accelerated breathing at high altitudes affects metabolism by aiding in the removal of gaseous excretions, such as carbon dioxide.

Aëronauts observed the acceleration of the pulse to be the first physiological change. They can reach a much higher altitude than mountain climbers without having any difficulty in sustaining respiration, as their muscular exertion is not so great. But the transition to the rarefied air is more sudden, and the increased, difficulty in breathing, which now appears although the aëronaut is generally unconscious of it at first, results from an insufficient expansion of the respiratory organs, which renders them incapable of admitting the requisite amount of rarefied oxygen The strength of his respiratory muscles is diminished; he finally loses control of his limbs, and his senses are dulled. This

was the experience of Eroce Spinelli, Sivel and Tissandier, who, on August 15, 1875, reached an altitude of 7,000 m. (23,750 ft.) with an atmospheric pressure of only 300 mm. in two hours. They followed Paul Bert's advice and inhaled oxygenated air, as a result of which their strength immediately revived.

After a longer sojourn in regions of high altitude the symptoms of mountain-sickness pass away, as respiration is gradually regulated to suit the conditions of the rarefied atmosphere. The change which this necessitates is easily explained. In order to breathe deeply it is necessary to expand the lungs more slowly, and this is only accomplished by means of continuous unconscious practice which strengthens the respiratory muscles. The members of Alpine clubs who make high ascents keep in practice by repeating their excursions frequently. Hence they are far less subject to mountain-sickness than those who have had no previous training.

The wonderful feats of Paul Guessfeldt, which are described in the German Rundschau of 1892, are a good illustration of the benefits to be derived from such a training. He breathed and moved without any inconvenience at an altitude of about 5,500 meters, where the atmospheric pressure is equal to only one-half of the ordinary pressure. In ascending Mt. Aconcagua, in Chile, he had no difficulty in breathing until after the altitude of 6,000 meters had been reached, and even then he was finally able to ascend to the summit, which has an elevation of nearly 7,000 meters, or 23,910 ft., an altitude at which aëronauts are compelled to have recourse to their supply of oxygenated air.

A distinguishing characteristic of the air of high altitudes as compared with that of lower regions is its freedom from moisture. The atmosphere is so dry on the plateaus of the Andes in Peru and Bolivia, where the altitude ranges from 3,600 to 3,900 meters, that the flesh of butchered cattle can be dried in the open air. The two explorers, D'Orbigny and Wedell, both report that the sheep which are killed there are split open and salted, after which they are hung up in the open air, and are dried in four or six days.

The ocean is the chief source of the moisture contained in the atmosphere; consequently the interior of the continents is drier than the coast regions; and in the same way the moisture decreases as we rise above sea level. The lower stratum of air up to about 2,000 meters (6,500 ft.) contains one-half of the whole amount of aqueous vapor in the atmosphere, and here the cloud-formations are densest and most frequent, while above this altitude the sky is much clearer.

It is a well-known fact that extreme dryness of the atmosphere stimulates the nervous system, making one feel brighter and more inclined for both physical and mental activity. The inhabitants of very dry regions, according to the reports of explorers, are free from any tendency to obesity.

In trying to escape from the hot air of the cities in the summer we look for a place which is situated higher above sea level, because we know it to be cooler. In the torrid zone, resorts with an elevation of from 2,000 to 3,000 m. are popular. In spite of being nearer to the sun, the air is cooler, as the sun's rays have practically no effect upon it. The air allows the rays to pass through it freely, but receives its warmth from the dark heat rays which are reflected from the earth after the sun has warmed it. The lower strata of air are, therefore, always warmer than the upper. But the plateaus of the highlands are cooler too, as well as the summits and crests, for their rarefied atmosphere is incapable of absorbing as much of the heat reflected by the earth as the denser atmosphere of the

lowlands. Although the surface of the earth receives more heat at high elevations, it is immediately reflected back into space without heating the air to a corresponding degree. This is evidenced by the fact that at high altitudes the difference of the temperature in the sun and in the shade is greater than in the lowlands. But the effect of the sun's rays is felt more keenly at a high elevation, so much so that persons staying at Davos can enjoy a sun-bath in a sheltered spot even in the cold of winter, although wearing much thinner clothing than at home.

It takes a visitor at Cerro de Pasco, in Peru, which lies at an elevation of 4,500 meters, ten or twelve days to thoroughly regulate his respiration to the conditions of the atmosphere. In case his suffering is greater at first, it often happens that he is compelled to make a temporary change of residence to a point some 1,000 meters nearer the level of the sea. Even during the descent he begins to breathe more easily and feels brighter and stronger.

The inhalation of air which has been artificially condensed, as in a pneumatic cabinet, produces quite similar sensations. An asthmatic patient placed in an atmosphere where the pressure has been augmented by nearly one-half will immediately be enabled to breathe more freely; respiration becomes slower; his excited nerves are quieted, and he feels imbued with renewed vigor.

The mechanical action of condensed air as it affects respiration is the reverse of the action which takes place in rarefied air. A higher atmospheric pressure facilitates the expansion of the lungs, and the condensed atmosphere, by delaying the egress of the air expelled during exhalation, finally effectuates a distended condition of the lungs. The pulse-beats become slower at the same time, and the veins, which were surcharged with blood under a diminished pressure, are now emptied more thoroughly. This is the cause of the decrease of congestive conditions in a pneumatic cabinet. The amount of oxygen which we inhale is increased in proportion to the increased condensation of the atmosphere, thereby enriching the blood. If the treatment is continued, this soon makes itself manifest by an increased appetite and a healthier complexion. The invalid gains in strength and vitality. Respiration is facilitated even outside of the cabinet, and by such observations we perceive that the employment of condensed air has after-effects, which supposition the spirometer confirms. A deeper and more quiet respiration has been observed in some cases after the elapse of one and even two years.

The air which is admitted into the pneumatic cabinets by means of air pumps can be kept at any degree of condensation. The cabinets, which are of various sizes, are arranged to admit from three to fourteen persons, and naturally great care is taken to have a good ventilation. They generally stand in the center of a lighted hall; their walls are composed of sheet iron and provided with windows which admit ample light for reading. The cabinets are used exclusively for the cure of catarrhal diseases, to facilitate the respiration of asthmatic patients, and to improve the condition of the blood of anæmic persons, in which cases the condensed air frequently proves beneficial after all other remedies have failed.

The first pneumatic cabinet was established somewhere in the thirties, at Montpellier, by a physicist named Tabarie, who later gave the management of it into the hands of a physician. Pravaz soon followed his example at Lyons, and the reports of the two scientists as to their observations made on healthy and diseased persons were presented before the French Academy and to the medical world in quick succession.

About thirty years later the idea of putting condensed air to this use spread from France to other countries of Europe, and the largest institution of this kind at present is at Reichenhall, the property of E. Mack, in which 53 persons can make use of the heightened pressure at the same time.

In 1841 M. Triger, a civil engineer, introduced in France the idea of using a heightened atmospheric pressure in building sub-aqueous works, and this gave an opportunity to observe what effect an atmospheric pressure which was much higher than that of a pneumatic cabinet would have upon the workmen. The work under pressure is carried on in an iron shaft, the sides and top of which are air-tight. It is sunk to the bottom, like a diving-bell, while the upper end protrudes above the surface of the water. The fresh air which is continuously pumped in from above expels the water below, leaving the bottom free to be worked upon. The shaft sinks deeper and deeper as the earth is removed, until there may be a pressure of $3\frac{1}{2}$ or nearly 4 atmospheres. A pressure of ten meters of water is equal to about one atmospheric pressure.

The effect of the condensed air upon the laborers was found to be surprisingly favorable up to a pressure of two atmospheres. The hard work was accomplished more easily and with less fatigue than in the open air, and in such exertions as running up a ladder they did not get out of breath. Even after working hours the men felt stronger and in better spirits.

But when the pressure exceeds that of two atmospheres the men begin to have certain unpleasant sensations, such as itching and pains and swelling of those muscles which are strained the most. These symptoms do not, however, appear while under the heightened pressure, but make themselves felt during the time that the men are under the normal pressure, and pass away again as they return to their work. The overseers are exempt from these effects. They receive instead a mental stimulus which is manifested by an increased impulse to talk.

If the atmospheric pressure is still further increased, the resistance against exhalation becomes stronger. The action of the respiratory apparatus is weakened by the increased distension of the lungs until it finally becomes almost imperceptible; speech is difficult, and whistling impossible. The result of the too rapid contraction of the lungs under a diminished pressure which prevents whistling is the same as that which follows when the egress of the air expelled by the lungs is delayed.

The enlivening influence on the workmen is diminished as soon as the pressure exceeds that of three atmospheres. The slow and imperfect performance of the respiratory function begins to have a detrimental effect upon the gaseous interchange which takes place in the lungs by causing the carbon dioxide to be retained in the blood. The laborers become more easily fatigued, and a decrease of appetite is followed by loss of flesh, if they continue the work. We find, therefore, that there is a limit to the condensation of air which a man cannot overstep without detriment to himself, but there is a wider limit in this direction than in that of rarefied air.

Experience proves that a temporary change from the normal pressure to an increased or diminished pressure is pleasant and also benefits vitality in various ways. We are able to ascend to any altitude at which the air is rarefied to the desired degree, but the privilege of choosing a denser atmosphere in which to live is denied us. It is only from a few places at very high elevations that convalescents can be sent down to a lower altitude where they quickly recover by inhaling air which is more condensed and contains a larger proportion of oxygen. The inhabitants of the

lowlands are confined to the pneumatic cabinet in their search for these benefits. From what has been said regarding the mechanical change which respiration undergoes we gather that a temporary employment of condensed air, besides its various other effects, would be a good preparation for the proper performance of the respiratory function in a more rarefied atmosphere.*

* Translated from the author's MS. by Henriette Weber, Columbus, O.

NOTES ON THE NATURAL HISTORY OF THE WILMINGTON REGION.

A BRIEF collecting trip to the vicinity of Wilmington, N. C., made about the middle of April, greatly impressed me with the natural history advantages of the region. I publish these few notes in the hope that they may be of service to other naturalists who think of visiting the Southern coast.

In Wilmington itself no one can fail to notice the admirable shade tree, the laurel oak (*Quercus laurifolia* Michx.), so common along the streets. This tree in Wilmington passes under the name of water oak; in South Carolina it is known as the Darlington oak. Its straight bole, symmetrical top and moderate size give it an elegance of shape well suited to city streets, and the impression of finish is heightened by the glossy aspect of the foliage.

From the city there runs a most excellent road, eight miles long, to Wrightsville, a settlement on the coast. The road is a well-kept shell road, smooth, hard, and good for bicycling. Scrub oaks, elms, long-leaf pines and cypresses edge it, and near the sound the full green heads of the live oaks are seen on all sides. In the open meadow-like places (savannahs) to the right and left of the road there grow in great abundance insectivorous plants, the most interesting members, to the general biologist at least, of that rich Wilmington flora made known through the labors of Curtis, Wood and other systematic botanists. The yellow-flowered pitcher plant, *Sarracenia flava*, dots the savannahs in all directions; its great flower (four inches wide) upheld by a scape one to two feet, making it a conspicuous object. The fly-trap, *Dionæa*, and sun-dew, *Drosera*, neither in flower at the time of my visit, are scattered thickly about. Intermingled with these are a blue and yellow species of butterwort, *Pinguicula*, their bright flowers standing out clearly against the (at this time) brownish savannah and often leading one to patches of *Dionæa* and *Drosera*, which otherwise would have been passed by unnoticed. These five insectivorous plants may sometimes be found growing together in a little patch of ground, scarcely larger than a square foot.

The topography of the Wrightsville district is that characteristic of the Carolina coast, and in a less degree of the Southern coast in general. A sound separates the mainland from a seaward strip of land, known as the 'banks.' Wrightsville, largely made up of houses occupied only during the summer, is on the mainland. Opposite it, on the banks, is a newer summer settlement. Between the two, the sound is crossed by a railroad trestle, the piles of which afford good collecting.

The sound something less than two miles wide, is divided into a narrow outer portion, adjoining the banks and known as the banks channel, and a wider inner portion, studded with sandy-mud shoals. The banks channel is a narrow but pretty boating ground, opening out to sea through two inlets, one recently made in a heavy storm. Along the inner edge of the channel lie some islands, the 'hammocks,' wooded with live oaks, about which jackdaws (*Quiscalus major*) were flying. This bird is said to spend the winter here.

At high water one can sail over many of the shoals of the inner part of the sound, but at low water the course from the mainland to the banks channel is a meandering one. The shoals are alive with worms, *Arenicola*, *Diopatra*, *Clymenella* and other annelids, along with the great *Balanoglossus*, were dug up in quick succession. The reddish egg masses of *Arenicola* lay about in abundance on the flats. The low water collecting in the shoal part of the sound is very easy. Pushing along in a skiff through the shallow channels between the flats, one finds starfish (*Asterias*), the red and white sea-urchins (*Arbacia* and *Toxopneustes*), abundant crabs and other common bottom forms. Scattered about over the bottom in great numbers is the interesting anemone, *Cerianthus americanus*. The tubes that were dug up were something over a foot in length; they contained animals, which of course had greatly contracted, about six inches long. This distinctively Southern actinia, originally found on the South Carolina coast by Professor Louis Agassiz (Verrill, Revision of the Polypi of E. Coast of U. S., p. 32. Mem. Boston Soc. Nat. Hist., Vol. I.), has been observed by Mr. Wm. Stimpson and Professor McMurrich at Beaufort, N. C., where I have seen it myself. It is, however, far more abundant at Wrightsville, and any one wishing to work out the life-history of this remarkable form could find no better locality than the latter place. I may add that the reproductive organs of the specimens I collected were very small. The breeding season probably comes on later.

Just before high water I towed in the neighborhood of the old inlet. As I had anticipated from previous experiences in Beaufort harbor at this time of year, not much of interest was in the water. Small hydromedusæ, crustacean larvæ, abundant *Sagittas*, make up the tow stuff. Later in the year, doubtless as at Beaufort, the towing is excellent. I am told that abundant large jelly-fish and Portuguese men-of-war make their appearance in August and September.

The sea-beach has a very gentle slope, and judging in part from specimens sent me by Mr. Chas. M. Whitlock, of Wilmington, many things of interest are to be had just beyond the line of breakers, where the sea is frequently calm enough to permit collecting. In the main the Wrightsville fauna is evidently very similar to that of Beaufort (see the lists in Studies of Biol. Lab. Johns Hopkins Univ., Vol. IV., No. 2, and the list of annelids by Professor Andrews, Proc. U. S. Nat. Mus. Vol. XIV., No. 852). I may add that some of the local collectors would recognize, from a description, many of the striking forms, such as *Chætopterus*, *Chalina arbuscula*, *Leptogorgia virgulata*, all of which may be had here.

UNIVERSITY OF NORTH CAROLINA.

CURRENT NOTES ON ANTHROPOLOGY.

PETRIE'S 'NEW RACE' IN EGYPT.

Two years ago (SCIENCE, August 28, 1895) I described the discovery by Mr. Flinders Petrie in Middle Egypt of remains which he attributed to an invading race about the twelfth dynasty, and which he was inclined to believe were Libyan stock.

Since then there has been considerable discussion of the subject, the general trend of which was in favor of Petrie's view. Dr. G. Schweinfurth, however, in the *Verhandlungen* of the Berlin Anthropological Society for January, attacks this theory, and claims that the remarkable stone artefacts unearthed in the tombs of the 'New Race' are such as are made to-day by the Ababde in the Thebaïs. He is inclined to the belief that the ancestors of these tribes in prehistoric times were the so-called 'New Race' and came from the Bedcha stock, near the coast of the Red Sea.

There are, however, a number of facts overlooked by Schweinfurth which indicate that the 'New Race' were conquerors of an older Egyptian civilization; nor is it likely that the Bedchas would have occupied so exclusively the left bank of the Nile, when their homes were east of its right bank. Petrie's supposition is still the most probable of any offered.

A PHILOSOPHIC SECT.

In the May number of the *Journal of the Anthropological Institute*, Mr. H. Balfour describes the sect of the Aghori fakirs in India. Their doctrine and their practice are based on the philosophic principle of the fundamental equality of all things, and, therefore, they are sticklers for absolute indifferentism. They disregard caste and creed, and receive accessions from the votaries of all religions. They are mendicants and despise property and labor. They eat with indifference carrion, offal or excrement, and as a cup or dish they use a fragment of a human skull, often quite fresh. In creed they are monotheists, believing in one god only, and have no respect for persons except the teacher or *guru*, who has initiated them into the sect. He gives each disciple a name, thus blotting out his past self.

It seems somewhat inconsistent that they should have a form of marriage, but other writers speak of their women as prostitutes. Originally, they seem to have been worshippers of Devi, the wife of Siva, in whose cult obscenity and bestiality were pushed to their furthest extremes.

D. G. Brinton.
University of Pennsylvania.

NOTES ON INORGANIC CHEMISTRY.

An account is given in *Nature* of the meeting of the International Congress on Technical Education held in London, June 15th–17th. The opening day was devoted to the teaching of chemistry. In one paper Dr. Otto N. Witt, of the Polytechnic School of Berlin, said he could not admit any fundamental difference in the methods of research of pure and applied chemistry; consequently he could not admit the necessity for a difference of instruction for the two. A well-organized instruction in pure chemical science would be the best preparation of any young chemist for his future career. Schools for producing specialists are not wanted; specialism comes as a matter of course in later life. Chemists are needed who embrace their science as a whole, and who are incapable of separating either practice from theory or theory from practice. Dr. Gladstone, speaking of evening schools, said that when the school was situated in the neighborhood of factories it would be allowable and even desirable that the illustrations should be chosen with some reference to the prevailing industry. This is a principle capable of wider application.

In a paper by Professor Lunge, of Zurich, the writer held that, to raise English chemical industry to the foremost rank, it is necessary that the technical management of chemical factories should not be left in the hands of 'rule-of-thumb' men, but should be entrusted to real chemists. These men should have a much fuller education than the majority of chemists seem to obtain at present in Great Britain, which means that they must spend more time and money on their training than they generally do. At college the student should receive a thorough training in scientific chemistry, taking this in its widest meaning, not merely as a 'testing' exercise. Next to this, but not to the same extent, he should be taught physics, mineralogy, technology, mechanics and the elements of engineering. Professor Lunge held that it was unwise for the common workmen or even the foremen to have a knowledge of chemistry or technology, as it is their duty

to simply carry out instructions, and not to meddle with the chemical process itself. Professor Silvanus P. Thompson, in discussing Professor Lunge's paper, urged that where a great industry is localized, science should be applied to that industry, and an institute should be put there devoted to monotechnical rather than polytechnical instruction. Training in research is absolutely necessary, and specific research should not be undertaken too soon by students who have not been taken through an all-round course in chemistry. Sir Henry Roscoe pointed out that England suffers chiefly from the failure of her manufacturers to see, as they ought to see, the importance of the highest scientific training for their employés. Scientific teaching has taken up a sound position already, and if manufacturers will only appreciate its value England can turn out scientific men as well as any country in the world.

THE last *Berichte* of the German Chemical Society contains a series of observations of the amount of carbon dioxid in the air of Sheffield, by W. Carleton Williams. The mean amount found in 142 determinations in the suburbs is 3.266 parts per 10,000, the maximum being 5.14 and the minimum 2.16. The average of 22 determinations in the center of the city is 3.9, with a maximum of 6.22 and a minimum of 2.80. These figures are higher than those observed in Paris (2.85), Dieppe (2.94) and Odessa (3.04), and only equaled by those in Dundee (3.9). As regards the conditions pertaining at the time of the experiment the following conclusions are drawn. During mist and snow the amount is increased; no difference is shown in rainy weather (previous observations on this point differ); a maximum (3.6) is reached in January, decreasing to a minimum (2.59) in April; the amount decreases with the increase of temperature—below 0°, 4.06; 0°–5°, 3.31; 5°–10°, 3.22; 10°–15°, 2.98—possibly due to increased fuel consumption in cold weather; increase with very high or very low barometer. These observations contribute to the view that the amount of carbon dioxid in the atmosphere is by no means constant under varying conditions.

G. SPEZIA contributes to the *Atti* of the Turin Academy an investigation on the action of water on quartz under pressure. Pfaff had shown, using quartz powder, that at 18° and 290 atmospheres' pressure one part of quartz dissolved in 4,700 parts of water; using plates of quartz, Spezia finds that at 25° and 1,750 atmospheres (in one experiment 1,850 atmospheres) in the space of over five months absolutely no quartz went into solution.

J. L. H.

SCIENTIFIC NOTES AND NEWS.

THE subject of Professor W. P. Mason's address as Vice-President of the American Association for the Advancement of Science (Section C., Chemistry) will be 'Expert Testimony.' The subject of Vice-President L. O. Howard's address (Section F., Zoology) will be 'The Spread of Land Species by the Agency of Man with especial reference to Insects.' The subjects of the other addresses have already been announced in this JOURNAL.

THE party from the zoological department of Columbia University reached Puget Sound, Washington, in the latter part of June, and gave a fortnight to the further exploration of the waters of the Sound. Upon July 8th they started for Sitka, Alaska, where they will remain from four to six weeks, returning to Port Townsend at the close of the season. The party includes Professor Wilson, Dr. Calkins, Professor Lloyd and five others.

PROFESSOR OSBORN has recently returned from a visit to the various parties sent out by the American Mueum of Natural History. The systematic collection of vertebrates this year is extended for the first time among the reptilia, and two parties are working in Kansas and Wyoming. Professor Osborn and Dr. Wort-

man made a survey of the Huerfano Tertiary Lake Basin, in southern Colorado, discovered in 1888 by Professor R. C. Hills, of Denver. The main Museum party has been stationed in the Equus Beds of northwestern Nebraska, where a very complete Pleistocene collection has already been obtained. This department of the American Museum has prepared an exhibit of enlarged photographs of eight mounted fossil skeletons in the Museum, and of twelve restorations designed by Charles Knight, for the International Exposition at Brussels. A similar series will be exhibited at the Geological Congress at Moscow, and at the meetings of the American and British Associations in Detroit and Toronto.

WE learn from *Nature* that the Sydney expedition to Funafuti, to make borings in the coral, projected and led by Professor David, started on June 2d, going by steamer to Fiji, and thence by sailing vessel to Funafuti. This expedition has been made possible by the liberality of the mining department of the government of New South Wales, which has supplied all the boring plant free of cost, and by the munificent gift from Miss Walker, of Sydney, of £500, and from the Hon. Ralph Abercrombie of £100, towards the expense of the expedition.

THE Park Board of New York City have finally adopted the plans of the managers of the Botanical Society for the Botanical Gardens in Bronx Park. R. W. Gibson and the Lord & Burnham Company have been appointed architects. The Board of Estimate has been requested to issue bonds to the amount of $500,000 to defray the cost of erecting the buildings.

DURING a lecture by M. Lacaze-Duthiers, professor of zoology at the Sorbonne, the oxyhydrogen generating apparatus exploded and two of the assistants, MM. Brumpt and Lancepaline were injured, the latter somewhat seriously.

THE Council of the Zoological Society of London have conferred the silver medal of the Society on Mr. Alexander White for his contributions to our knowledge of the fauna of Nyassaland.

ON the occasion of his retirement from the chair of practical chemistry in the School of the Pharmaceutical Society of Great Britain, Professor John Attfield, F.R.S., has been the recipient of a testimonial consisting of an autograph album and silver plate. The former contained the names of eminent scientific men of England and the Continent.

MR. JAMES F. BABCOCK died at Dorchester, Mass., on July 19th, at the age of fifty-three years. He was formerly professor of chemistry in Boston University. During his terms of office as State Assayer and Inspector of Milk he made great improvements in methods of testing. He was the inventor of the fire extinguisher which bears his name, and was well known as a lecturer on popular scientific subjects.

MR. CHARLES F. CROCKER, whose death in San Francisco has been announced, was a regent of the University of California and had made many gifts to public and scientific institutions, including Lick Observatory. His will does not contain public bequests.

THE death is announced of Professor W. Preyer, the eminent physiologist, at Wiesbaden, at the age of 56 years.

WE regret to record the following deaths: M. Chudzinski, professor in the Paris School of Anthropology; Dr. E. Le Gros, professor of physiology at the new University of Brussels, known for his contributions to ophthalmology, aged 36 years; Professor W. Marmé, director of the Pharmacological Institute of Göttingen; Dr. Giuseppe Fissore, sometime professor of pathology in the University of Turin, aged 82 years, and Dr. M. Josef Oertel, professor of medicine at Munich.

THE United States Civil Service Commission announces a competitive examination to fill the vacancy in the position of Supervising Architect of the Treasury. The salary of this position, which is one of the most important and responsible under the government, is $4,000 per annum, and it is hoped that architects of high attainments and reputation may be induced by these considerations to enter the competition. It is the desire of the Department to secure a practical architect of high administrative abillty to direct and supervise the work of the office force as well as the contract work

done on public buildings throughout the country.

IT is reported that the Secretary of Agriculture will ask Congress at its next session to authorize the establishment of an Agricultural Experiment Station in Alaska. Suitable scientific experiments would be of great value in showing what agricultural products and domestic animals could be introduced to advantage.

ACCORDING to the New York *Evening Post*, George A. Brill of Poughquog, Dutchess county, who was graduated from Cornell University in 1888, recently received a cable despatch from Li Hung Chang offering him a liberal sum to organize and manage a model farm in China under the government. He will accept the offer, and will soon leave for China to enter upon his duties.

PROFESSOR BESSEY writes in the *American Naturalist* that he knows from many years of personal experience, and this not in an old and wealthy community, that the purchase of good compound microscopes (duty free), and the installation of small but efficient laboratories in secondary schools, is as easily accomplished for botany as is the purchase of necessary apparatus and the fitting-up of proper laboratories for chemistry. In the new State of Nebraska nearly every accredited high school is now using the compound microscope in the study of plants selected as types of all the greater groups of the vegetable kingdom.

AT the request of Mr. Melvil Dewey, on behalf of the American Library Association, the U. S. government has agreed to issue postal cards of the standard library size for index cards.

THE second International Library Conference was opened on July 13th in London by the Lord Mayor. Sir John Lubbock gave the presidential address. Papers were subsequently presented by Mr. J. T. W. MacAlister, of the Royal Medical and Chirurgical Society of London; by Mr. Henry Tedder, Mr. Herbert Jones, Mr. Alderman Rawson, Mr. Melvil Dewey and others.

AT the recent conversatzione at University College, London, apparatus to be used in a course in experimental psychology was exhibited. The course will be given under the direction of Professor James Sully and Dr. W. H. R. Rivers.

LORD KELVIN has written a letter to the London *Times* stating that in his address at the Pender memorial meeting (quoted in the last issue of this JOURNAL) he inadvertently did serious injustice to the late Sir Curtis Lampson when he said that it was owing to Mr. Pender alone that the Atlantic Telegraph Company was kept afloat from 1858 to 1864. In fact, a large part of the heavy burden of keeping the original Atlantic Telegraph Company alive in the disheartening circumstances of the failure of the 1858 cable, after the short time of its successful working, was voluntarily undertaken by Mr. Lampson when he and Mr. Pender continued to act as directors and nearly all the others, incluing Lord Kelvin himself, resigned.

THE new underground railway in London, extending from Liverpool street to Bayswater, has been an engineering feat of considerable scientific interest. The tunnels are steel tubes 11 feet 6 inches in diameter driven through the clay, each tunnel containing one track. The electric equipment, including the elevators, is supplied from America.

THE *Railway and Engineering Review*, one of the best of the technical journals, publishes in its issue of July 3d an editorial article two columns in length advocating the use of the metric system and maintaining that no great inconvenience would be caused in its practical application.

UNIVERSITY AND EDUCATIONAL NEWS.

THE Pennsylvania Legislature appropriated $200,000 to Lehigh University, and Governor Hastings has signed bills granting $150,000. The funds of Lehigh University are chiefly in stocks of the Lehigh Valley Railroad left by the late Asa Packer and no dividends have been paid for three years.

THE will of the late Alexander Wheelock Thayer gives $30,000 (subject to a small annuity) to Harvard University as an endowment fund to assist poor students.

MR. D. A. BEAMER has given $10,000 to the Laman Missouri Educational Association. The Boston *Transcript*, in announcing this gift, remarks: "The Association has a capital of $20,000, fully paid up, and will establish and operate an up-to-date college of a high order!"

THE following advancements and new appointments in the scientific departments of the University of Texas for the year 1897–'98 have been made: Thomas U. Taylor has been advanced from the grade of associate professor of applied mathematics to that of professor; Dr. Sidney E. Mezes from the grade of adjunct professor of philosophy to that of associate professor; Dr. Henry Winston Harper from the grade of adjunct professor of chemistry to that of associate professor, and W. W. Norman from the grade of adjunct professor of biology to that of associate professor. Dr. Joseph Baldwin, the venerable professor of pedagogy, has been made emeritus professor, and Mr. William S. Sutton, City Superintendent of the Houston Schools, has been elected professor of pedagogy; Mr. E. P. Schoch returns to the University as instructor in chemistry.

AT the Oshkosh Normal School the following appointments have been made: H. Fling, Ph.D., Chicago, to the chair of biology and chemistry; Frank A. Mitchell to the chair of geography; F. D. Sherman, Ph.D., Leipzig, to the chair of pedagogy and psychology.

AT a meeting of the electors to the Savilian professorship of geometry held on July 8th, Mr. William Esson, M. A., F. R. S., fellow of Merton College, was elected professor in the room of the late Professor Sylvester.

MR. ERNEST WILLIAM MACBRIDE, fellow of St. Johns College, Cambridge, and senior demonstrator in the zoological laboratory of the University, has been appointed to the new chair of zoology in McGill University, endowed by Sir Donald A. Smith. Mr. MacBride has held the Hutchinson studentship for research at Cambridge and was awarded the Walsingham Medal in 1895. He has published an important series of Monographs on the Echinodermata.

UNDER the will of Mrs. Gee, widow of the late Robert Gee, lecturer on the diseases of children in the medical school associated with University College, Liverpool, that college receives over £7,000 for the purpose of advancing the medical department and promoting study and research in medical science. It has been decided by the medical faculty to institute a Robert Gee fellowship in anatomy of the value of £100 for one year, and four entrance scholarships of £25 each for one year.

THE Council of St. Hugh's-hall, Oxford, has recently accepted from Miss Clara Evelyn Mordan a donation of £1,000 to found a scholarship to be called by her name.

THE *Lancet* states that Professor Engelman, in taking the late Dr. Du Bois-Reymond's chair at Berlin, is arranging certain changes in the Physiological Institute and its four departments. The first, for microscopical and biological work, will remain under the charge of Professor Fritsch. Similarly, the second, for chemical physiology, will continue under its present director, Professor Thierfelder. The third, for special physiology, will be greatly enlarged, and the professor himself will take part in its work in conjunction with the present director, Dr. Immanuel Munk. The fourth department, for physical physiology, will also be largely increased; it will be called the Department for the Physiology of the Sensory Organs and will remain under the direction of Professor König. In addition to extensive new buildings, the supply of apparatus will be largely augmented. The lectures will be given by the professor in a course running through two semesters, but during the last four weeks in the summer Professor König will lecture on the sensory organs, and during the first four weeks of the winter Professor Thierfelder will lecture on physiological chemistry.

PRESIDENT ANDREWS, of Brown University, has been requested by a committee of the Board of Trustees not to discuss the question of the free coinage of silver, and has consequently been compelled to resign from the presidency of the University. The trustees did not base their action on the supposed evil effects of President Andrews' teaching, but on the alleged ground that the University had, through the

expression of his views, lost gifts and legacies and might lose more. The occurrence is extremely regrettable. It might have been better if President Andrews had not felt called upon to advocate the views of a political party unpopular in Rhode Island, but if the trustees have by their action increased 'gifts and legacies' to Brown University they have done harm to the cause of education. The first part of President Andrews' letter of resignation is as follows:

Believing that, however much I might desire to do so, I should find myself unable to meet the wishes of the corporation as explained by the special committee recently appointed to confer with me on the interests of the University without surrendering that reasonable liberty of utterance which my predecessors, my faculty colleagues and myself have hitherto enjoyed, and in the absence of which the most ample endowment for an educational institution would have but little worth, I respectfully resign the presidency of the University, and also my professorship therein, to take effect not later than the first day of the approaching September.

DISCUSSION AND CORRESPONDENCE.

AMPHIBIA OR BATRACHIA.

Professor Gill in his excellent address 'Some Questions of Nomenclature,' delivered at the Buffalo meeting of the American Association for the Advancement of Science,* makes the following remarks about the name *Amphibia* (p. 600): "Why should the name Amphibia disappear and Batrachia and Reptilia usurp its place? Amphibia is a far better name for the Batrachia, and in every way defensible for it. The name had especial relation to it originally, and it was first restricted to it as a class." In the Editor's Table of the *American Naturalist*, December, 1896, p. 1027, we read the following from the pen of Professor Cope: "It is difficult to eradicate from scientific literature a name or word which has become current, even after it has been found to be an expression of ignorance or error. Thus some names introduced into zoology die hard. Perhaps the most pestilent pretender of the list is the word Amphibia, which is so frequently used instead of the proper name of the class Batrachia. The name Amphibia was originally applied to a combination of the Reptilia and Batrachia, before the fundamental differences between the two were known. When the Batrachia were first separated from the Reptilia the new name was naturally applied to the new division, and the name Amphibia would have been more applicable to the larger division of its former self, *i. e.*, the Reptilia. As, however, its definition accorded with neither the Reptilia nor Batrachia, it was not used for either; nor was it introduced to take the place of Batrachia with a definition, until a few years ago by Huxley. This was done in defiance of the universal usage of naturalists at the time, and probably in ignorance of the real state of the case, since it frequently happens that men engaged in the real work of biological science find questions of names irksome and stupid. Nevertheless it is a distinct advantage always to have but one name for one thing, and that name should be the oldest which was applied to the thing in question as determined by the definition given. Applying this principle, the name Batrachia has a quarter century priority over Amphibia."

I shall show that the opinion of Professor Gill is the only one that can be accepted.*

In the 10th edition of Linné† we have the following:

Classis III. *Amphibia.*

I. *Reptiles* os respirans: Pedes quattuor.

103, *Testudo*; 104, *Draco*; 105, *Lacerta*; 106, *Rana.*

II. *Serpentes,* os respirans, Pedes Pinnæve nullæ.

107, *Crotalus*; 108, *Boa*; 109, *Coluber*; 110, *Anguis*; 111, *Amphisbæna*; 112, *Cæcilia.*

III. *Nantes,* Spiracula lateralia, Pinnæ natatoriæ.

113, *Petromyzon*; 114, *Raja*; 115, *Squalus*; 116, *Chimæra*; 117, *Lophius*; 118, *Acipenser.*

The next author of importance to be mentioned is Alexandre Brogniart. His 'Essai

* Science, N. S., Vol. IV., No. 95, Oct. 23, 1896, p. 581–601.

*Nine years ago I followed Cope (Beiträge zur Morphogenie des Carpus und Tarsus der Vertebraten I. Theil. Batrachia. Jena, Gustav Fischer), but later I found that I was mistaken.

† Caroli Linnæi Systema Naturæ. Tomus I. Editio Decima, Reformata Holmiæ. 1758. Pp. 194–238.

d'une classification naturelle des Reptiles', was published in 1799.*

Brogniart divides the Reptiles into four orders: *Chéloniens*, *Sauriens*, *Ophidiens*, *Batraciens*, and gives the following characters: (Bull. Sciences Soc. Philom, No. 35, pp. 81–82. 1800):

"1er Ordre: Les *Chéloniens* (il renferme les tortues). Ces Reptiles n'ont point de dents enchâssées, mais leurs mâchoires sont enveloppées de gencives cornées tranchantes, leur corps est couvert d'une carapace. Il est bombé. Ils ont deux oreilettes au cœur, un estomac plus volumineux que les autres reptiles, un canal intestinal garni d'un cæcum, ils s'accouplent et pondent des oeufs à coquille calcaire solide. Ils se nourissent en' grande partie de végétaux."

2e Ordre: Les *Sauriens* (renferment les crocodiles, iguane, dragon, stellion, gecko, caméléon, lézards, sinque, chalcide).

Tous ces animaux ont des dents enchassées, deux oreilettes au cœur, des côtes et un sternum, le mâle n'a un organe extérieur de génération; ils s'accouplent réellement, pondent à terre des oeufs à coquille calcaire, d'où sortent des petits qui ne subisent pas de métamorphoses. Ils ont des plaques écailleuses ou des écailles sur le corps.

3e Ordre: Les *Ophidiens* (renferment les genres connus sous le nom général de serpents).

Ils se rapprochent plus des reptiles des premiers ordres que de ceux du quatrième, comme eux ils ont de longues côtes arquées, le mâle a un organe extérieur de génération, ils s'accouplent réellement et pondent des oeufs á coquille calcaire d'où naissent des petits en tout semblable à leurs parents; mais ils différent des Sauriens, parce qu'ils n'ont qu'une oreillette au cœur, point de sternum, que les mâles ont une verge double, quils pondent des oeufs à coquille calcaire molle et qu'ils n'ont point de pattes.

4e Ordre: Les *Batraciens*, (contenant les crapauds, les raines, les grenouilles et les salamandres).

Ces animaux différent autant des trois premiers ordres, qu'ils se conviennent entre eux, et l'auteur prouve que les salamandres qu'il a placées dans cet ordre, n'ont d'autre analogie avec les lézards, parmi lesquels on les avait mises, que d'avoir comme éux le corps allongé, des pattes et une queue.

Tous ces reptiles ont d'ailleurs une seule oreillette du cœur, points de côtes ou seulement des rudiments de ces os, la peau nue et des pattes, le mâle n'a aucun organ extérieure de génération et il n'y a point d'accouplement réelle, la plus part du temps les oeufs, sont fécondés hors du corps de la femelle. Ces oeufs sont sans coquille et pondus dans l'eau; les petites qui en sortent ont des branchies à la manière des poissons, et différent de leurs parents pendant les premiers moments de leur vie, ils se rapprochent par cela même des poissons; ces animaux doivent donc être placés dans l'ordre naturelle de la fin de la classe des Reptiles et immédiatement avant celle des poissons."

The close relationship between the frogs and toads and the salamanders had already been observed by Laurenti (1768) and Lacépède (1788–89), but they did not make any use of this fact in their classifications. It is the merit of Brogniart to have united these forms in a single order of his reptiles, which he called *Batraciens*. At the same time it is evident that he did not oppose the order Batraciens to the rest of the *Reptiles*, but gave it the same value as to the single orders *Chéloniens*, *Sauriens* and *Ophidiens*.

The first Latin names were given to these orders by Treviranus in 1802 and by Shaw in the same year.

Treviranus* uses the name *Amphibien* for the

*Brogniart, Alexandre, Essai d'une classification naturelle des Reptiles. Magazin encyclopédique ou Journal des Sciences, des Lettres et des Arts, rédigé par A. L. Millin. Tome V., pp. 184–201, 1799, reprinted in Bulletin des Sciences, par la Société Philomatique, No. 35, Iere Partie, pp. 81–82, Paris, Pluviose, an 8 de la République. IIe Partie No. 36, pp. 89–91, pl. VI. Ventose, an 8 de la République. (January 21st–March 19th, 1800.) The same paper, more extensive, was published in Mémoires présentées à l'Institut des Sciences, Lettres et Arts, par divers Savans, et dans les Assemblées. Sciences mathématiques et physiques, Vol. I., pp. 587–637, 2 pl., Paris, XIV.—1805; also separate, Paris, Baudouin, Imprimeur de l'Institut National. Prairial An XIII.—1805.

* Treviranus, Gottfried Reinhold, Biologie, oder Philosophie der lebenden Natur für Naturforscher und Ärzte. Bd. I., pp. 260–265 Göttingen, 1802.

whole group, and following Brogniart he divides it in four orders:

I. Schildkröten. *Testudines.*
II. Eidechsen. *Lacertæ.*
III. Schlangen. *Serpentes.*
IV. Frösche. *Ranæ.*

Shaw * uses the same names for the four orders of his *Amphibia* in the following order: I. *Testudines.* II. *Ranæ.* III. *Lacertæ.* IV. *Serpentes.*

We see the *Latin* name *Batrachia* was not used at all by Brogniart, as stated by Professor Cope in 1889 (Batrachia of North America, p. 17). The first *Latin* name for the order is *Ranæ*, Treviranus, and if we would follow Cope's opinion about this question we should have to call the class *Amphibia Ranæ*.

In 1804 Latreille † published his 'Tableau méthodique des Reptiles.'

Classe troisième.
Reptiles, REPTILIA.

I. Des pattes, ayant des doigts onguiculés, ou point des pattes; jamais de branchies ni de métamorphose.

Ordre I. *Chéloniens*, CHELONII.	Des pattes; corps enveloppé dans une boîte osseuse.
Ordre II. *Sauriens*, SAURII.	Des pattes; corps nu.
Ordre III. *Ophidiens*, OPHIDII.	Point des pattes.

II. Doigts des pattes n'ayant pas d'ongles; des branchies, du moins pendant un temps; de métamorphose.

Ordre IV. *Batraciens*, BATRACHII.

We see, that Latreille divides the Reptilia in two groups, without giving special names to them. The first group contains the Orders *Chelonii* (*Testudines*, Treviranus, Shaw, 1802), *Saurii* (*Lacertæ* Treviranus, Shaw), and *Ophidii* (*Serpentes* Treviranus, Shaw); the second one the order *Batrachii** (*Ranae* Treviranus, Shaw).

Two years later, in 1806, C. Duméril † used the Latin names: Class, *Reptilia*, with the orders, *Chelonii*, *Saurii*, *Serpentes*, *Batracii.*

Gravenhorst, ‡ in 1807, calls the orders: *Chelonia*, *Sauria*, *Ophidia*, *Batrachia.* §

Oppel ‖ opposed the 'Batraciens' to the other Reptilia, as can be seen from his diagnosis, but he did not give any special names to the combined opposed orders.

Classis REPTILIA. Animalia vertebrata; pulmonibus; sanguine frigido; pilis, mammellis, plumisque carentia.

Corpus
- obtectum
  - testa, sternoque .... I. *Testudinata* (Klein).
  - squamis, costis proprie dicti .... II. *Squamata* (Oppel).
- nudum, *i. e.*, nec testa, nec squamis; genitalia exteriora nulla; metamorphosis... III. *Nuda* (Klein).

Oppel was also the first one who placed the *Cœcilians* in the Amphibia; he also placed *Anguis* in the *Lacertilia.* The affinity between *Anguis* and the *Lacertilia* had been recognized, however, already one year before by *Lehmann.* ¶

Now follows the important paper of de Blainville, ** published in 1816. He divides the reptiles into two classes or subclasses, as will be seen from his diagram.

* Shaw, George. General Zoology or Systematic Natural History, Vol. III., Part I., Amphibia, p. 5. London, 1802.

† In the Nouveau Dictionnaire d' Hist. Nat., Vol. 24, p. 61.

*This is the first occurrence of the Latin form of Batraciens Brogniart.

¶ Lehmann, C. D. W. Über die Zerbrechlichkeit der Blindschlangen und die Übereinstimmung des inneren Baues derselben mit den Eidechsen. Magaz. der Gesellsch. Naturf. Freunde. I-Berlin. Jahrg. IV., pp. 14–31, 1810.

**Blainville, H. de. Prodrome d'une nouvelle distribution systematique du règne animal. Bulletin des Sciences par la Société Philomatique de Paris. Année 1816, pp. 113–124.

Classes III. et IV. *Reptiles* Hétéro ou Erpétozoaires. Squammifères et Nudipellifères.

Ire Sous-Classe *Ornithoïdes,* Ecailleux. ou IIIe Classe *Squammiferes.*	O. I. *Chéloniens* ou Tortues.	
	O. II. *Emydo-Sauriens,* ou Crocodiles.	
	O. III. *Bispeniens*	Ier Sous-O. Sauriens.
		IIe Sous-O. Ophydiens.
IIe Sous-Classe *Ictyoïdes* Nuds ou IVe Classe *Nudipelliferes*	O. I. Batraciens, ou Grenouilles.	
	O. II. Pseudosauriens, ou Salamandres.	
	O. III. Amphibiens, ou les Protées et les Sirènes.	
	O. IV. Pseudophidiens, ou Cœcilies.	

De Blainville makes the following very interesting remarks:

Les noms d'*Ornithoïdes* et d' *Ictyoïdes* employés dans le cas ou les reptiles seraient considerés comme une seule classe, indiquent que les premiers sont formés d'après le plan des oiseaux, et les seconds d'après celui des poissons. P. 119.

Merrem * (1820) divides the *Amphibia* Linné into two classes:

1. *Pholidota:* Corpus *pholide tectum.*

The *Pholidota* contain the orders: *Testudinata, Loricata, Squamata.*

2. *Batrachia:* Corpus *glabrum* aut *verrucosum.*

The *Batrachia* the orders: *Apoda, Salientia, Gradientia.*

The group *Amphibia* Linné is still retained, but it is divided into two classes: *Pholidota* and *Batrachia.*

Two years later, in 1822, de Blainville † separated completely the Amphibia from the Reptilia. Here is his general classification of Vertebrates (plate 2):

TYPE I.

OSTÉOZOAIRES ou A. VERTÉBRÉS.

Sous—Type I.	*Vivipares.*
Homme.	
Piliféres.	MAMMIFÉRES.
Sous—Classe I.	*Monodelphes.*
Sous—Classe II.	*Didelphes.*
Sous—Type II.	*Ovipares.*
Pénniféres.	OISEAUX.
Squammifères.	REPTILES.
Nudipellifères.	AMPHIBIENS.
Pinnifères.	POISSONS.

The special classification of the *Reptilia* and *Amphibia* is given in the following (plate 5).

Type I, OSTÉOZOAIRES.

Sous-Type II, OVIPARES.

Classe IIIe; les REPTILES.

REPTILES
- Ier degré d'organisation ou ordre CHÉLONIENS, ou Tortues. Les doigts
  - réunis en moignon, les *T. terrestres* (Tortue)
  - distinct, peu palmés, les *T. de marais* (Emyde, Chelyde)
  - distinct et bien palmés, les *T. de fleuves* (Trionix)
  - réunis en nageoir les, les *T. marines* (Chélonée, Demochélyde,
- IIe degré d'organisation ou ordre EMYDOSAURIENS, ou Crocodiles. Le museau
  - large et cour, Les *Caimans*
  - un peu long, les *Crocodiles*
  - très long, les *Gavials*
- IIIe degré d'organisation ou ordre SAUROPHIENS ou Bispéniens
  - Ier Sous-Ordre *Les Sauriens*
    - Les *Geckoïdes*, Les *Agamoïdes*, Les *Iguanoïdes*, Les *Tubinambis*
      - normaux, Agame, Basilic, etc.
      - anomaux
        - p. grimper
        - Caméléon
        - p. voler Dragon
    - Les *Lacertoïdes* ....
      - Tétrapodes
      - Dipodes
      - Apodes
  - IIer Sous-ordre Les *Ophydiens*
    - *Dipodes*.............................*Bimanes*
    - Apodes
      - sans dents vénim La quesu
        - conique
          - *Amphisbêne*
          - Grimpeurs ou *Boas*
          - *Couleuvres*
        - comprimie, *Pêlamides*
      - poruvus de dents vénim La queue ..
        - comprimie *Hydrorhides*
        - conique
          - *Viperes*
          - *Léthiféres*

* Merrem, Blasius. Tentamen Systematis Amphibiorum. Marburgi, MDCCCXX.

† Blainville, Ducrotay de, De L'organisation des Animaux, ou Principes d'Anatomie Compareé. Tome I. Contenant la Morphologie et l'Aistésologie Paris, 1822 (pl. 2 and pl. 5 at the end of the volume). This is the only volume that has been published.

Classe IV^e; LES AMPHIBIENS

AMPHIBIENS
- I[er] degré d'organisation ou ordre BATRACIENS .... Sous-ordre
  - I. *Aquipares.* Rainette, grenouille, Crapaud
  - II. *Dorsipares.* Pipa.
- II[e] degré d'organisation, ou ordre PSEUDOSAURIENS, ou Salamandres.
- III[e] degré d'organisation, ou ordre SUBICHTHYENS. Les Protées, Sirènes.
- IV[e] degré d'organisation ou ordre PSEUDOPHYDIENS, ou Coecilies.

Three years later Latreille* used the Latin names *Reptilia* and *Amphibia* for de Blainville's classes *Reptiles* and *Amphibiens*, and these names ought to be used. Gray† in the same year, but later used the same names as distinct classes.

This name is used to-day all over Europe, France excepted.

Latreille's characters are the following:

P. 90. "*Première Classe.* REPTILES. REPTILIA.

"Ils ne respirent, et en tout temps, que par des poumous. Le cœur a deux ventricules et deux oreillettes. Les mâles ont une verge quelquefois double ou fourchue et s'accouplent. Plusieurs sont sujets á des mues complètes, ou se défont de leur peau, mais aucun n'éprouve de métamorphose. Le corps est plus souvent garni d'écailles ou emboîté; les pieds sont toujours armés d'ongles très-sensibles. La coque des oeufs est dure ou du moins coriace."

P. 103–14. "*Seconde Classe. Amphibiens.* AMPHIBIA.

"Ici les deux poumons sont accompagnés, soit dans le jeune âge, soit pendant toute la vie, de branchies. Le cœur n'a qu'un ventricule et qu'une oreilette, tant que les branchies persistent, un tronc artériel et dorsal tient lieu du ventricule qui manque, savoir la gauche il est remplacé, lorsqu' elles disparaissent, par une artère dorsale. Les mâles n'ont point de verge. L'accouplement n'est que similué, c'est-à-dire qu'il ne consiste que dans de simples embrassements, durant lesquels les mâles fécondent les oeufs, á mesure qu'ils sortent. Les petits naissent sans pattes, et subissent de véritables métamorphoses. La peau est toujours nue, et les ongles des pieds sont nuls ou rarement sensibles. Les oeufs sont réunis, et leur coque est membraneuse. Ces animaux vivent pour la plupart dans les eaux ou les lieux humides."

CORRECTION CONCERNING MR. RHOADS' USE OF THE NAME BASSARISCUS RAPTOR (BAIRD).

IN a recent paper in the Proceedings of the Biological Society of Washington* I quoted two statements, which were in part contradictory, from a paper by Mr. S. N. Rhoads respecting the proper name for the Oregon Bassarisk. In so doing I made a stupid blunder, for one of the statements in question was quoted by Mr. Rhoads, whose own remarks in this particular were not inconsistent.

SCIENTIFIC LITERATURE.

Report on Vital and Social Statistics in the United States at the Eleventh Census, 1890. Part II., Vital Statistics. Cities of 100,000 Population and Upward. By JOHN S. BILLINGS, M.D. Washington, 1896 [Received May, 1897], pp. 1181.

Now that statistical studies of variation and

the phenomena of life are coming into so much favor among students of evolution, the present volume possesses a distinct value as a biological treatise, in addition to its obvious practical utility. It may serve at once as an encouragement and a warning to ardent statisticians, because, while many of the facts it sets forth are important and interesting, the closer it is studied the stronger grows the conviction that vital statistics need to be examined with extraordinary caution before being accepted at their 'face-value.' *Homo sapiens* is an animal whose habits are better known to us than those of any other, and we have exceptional facilities for estimating the factors which control his development and evolution. Accordingly, we readily perceive the more important probable sources of confusion in the statistics, as, for example :

(1) The 28 cities of the size indicated in the title had an aggregate population of 9,697,960, of which 4,850,653 were males and 4,847,307 females. Thus it might be inferred that the males of the human species were more numerous than the females, but for the recollection that large cities attract great numbers of men who either have no families or leave them elsewhere. Taking the cities separately, the majority had more females than males, but the following eleven had an excess of males: Buffalo, Chicago, Cleveland, Denver, Jersey City, Kansas City, Minneapolis, Omaha, Pittsburg, St. Louis (white) and St. Paul. It is significant that while Omaha had a population of 80,108 males and only 60,344 females, those under one year of age consisted of 1,411 males and 1,422 females, showing an excess of female births, in accordance with current expectations.

It is, however, very remarkable to find that in a number of cities there was an excess of male babies under one year of age, showing apparently an excess of male births. Thus Jersey City had 2,007 males and 1,966 females under one year; Chicago had 15,281 males and 14,823 females under one year. But this result is further complicated by the fact that there was a considerable excess of male mortality under one year; thus in Chicago the deaths under one year were 233.95 males and 190.72 females per 1,000 population of corresponding age. In every city the male mortality under one year exceeded the female, often greatly exceeding it. Thus including still-births, we get the following striking results:

Total deaths under one year.

	Males.	Females.
Buffalo,	1,069	817
Cleveland,	1,155	835
Philadelphia,	3,707	3,055
New Orleans,	1,084	844
and so forth.		

Now how are we to account for an excess of male births, combined with a remarkable excess of male mortality, during the past year? I have heard it stated that the slightly larger average size of the male head leads to an increase of the number of still-births, but this obviously will only account for a small proportion of the facts here before us. It seems to the present writer that some light may be thrown on the problem by the theory, adopted by some biologists, that the sex is determined at an early age by the conditions of the nutrition of the germ, favorable conditions producing a preponderance of females, unfavorable of males. If this is so, immediately we see the meaning of the above statistics. Omaha, which was the most healthy of the towns discussed, according to the data given, had an excess of female babies; other cities, notoriously containing unhealthy and crowded wards, show an excess of male babies. Further, if disadvantageous conditions lead to an excess of males, it is easy to understand why those males, on the average, should be less able to survive the first year. Hence the excess of male deaths, even when there was an excess of female births. It is to be supposed that those families and wards in which occurred the greater part of the male deaths would show an excess also of male births, though the city as a whole might not show it.

(2) Comparing 1880 with 1890, there is shown a great increase of infant mortality. Thus, for example:

Proportion of deaths under 1 year per 1000 births.

Newark,	under	150	in	1880,	over	250 in 1890
Jersey City,	"	175	"	"	"	225 " "
Denver,	"	125	"	"	"	200 " "
Rochester	"	100	"	"	"	150 " "
and so forth.						

Only three or four cities showed improvement, the most marked being St. Louis.

In studying these facts, there seems to be no escaping the conclusion that infant mortality in the large cities is largely on the increase, but it is probable that meteorological conditions may have affected the statistics, *e. g.*, it was perhaps wetter in 1890 than in 1880. However, on examining the causes of mortality for the two years, we get clearer evidence. 1890 shows a decided increase in 'inanition,' and also 'debility and atrophy.' There is also a marked increase in bronchitis and pneumonia. There is a decrease in convulsions and also in cholera infantum as compared with 1880.

(3) It appears that the colored have an almost uniformily higher death-rate than the whites; and this, as a general rule, is no doubt true; but the negro is known to be less susceptible to malaria than the white, yet, owing to his mode of life, his mortality from this cause is much greater in the cities discussed. Again, it appears from the tables that the death-rate of the native whites is greater than that of the foreign whites in most cities, but, as Dr. Billings points out, this must be connected with the fact that the native whites include a much larger proportion of young children. It is interesting to note that in New Orleans the death-rate of the foreign whites was much greater than in any other of the cities, while that of the native whites was less than in many of the cities. In connection with this we observe that the death-rate from malaria in New Orleans was more than double that in any other of the cities, and that it was much greater among the foreign whites; hence it is fair to assume that the native whites of New Orleans exhibit the results of evolution against this disease.

It may be here remarked that the mortality from typhoid fever was greater in the great cities of the United States than in those of England, France or Germany; and in the United States the foreign-born suffered markedly more from this disease than the native-born. Hence perhaps we may assert that the natives of the United States exhibit the results of evolution against typhoid an evolution more marked than that of European nations.

The death-rate of the colored from consumption was more than twice as great as that of the whites. Curiously, it was about twice as great among the children of mothers born in Ireland as among those of mothers born in Germany, and more than three times as great as among those of mothers born in the United States. This may be largely due to the manner of life of the Irish, but it does appear that they are naturally more susceptible to this disease than Germans or Americans. Erroneous conclusions might be drawn from the fact that Denver has a much higher death-rate from consumption than Pittsburg or Kansas City, did we not remember that very many consumptives go to Denver and die there.

In another part of the book are given colored maps of the cities, showing by different degrees of shading the death-rates in the several wards. Information is also given which enables one to form some opinion as to the causes of the remarkable differences between the healthfulness of the wards in all of the cities. These and many other matters might be discussed at length, but enough has been said to show that Dr. Billings' volume should be of great value not only to social reformers, but also to biological students. It may be that in the study of the facts these different classes of individuals will find a common ground, and the teachings of science will ultimately be heard in no uncertain way from the political platform, setting forth truths which will surprise many comfortable and self-satisfied individuals.

T. D. A. COCKERELL.

MESILLA, N. M., June 25, 1897.

GEOLOGIC ATLAS OF THE UNITED STATES. FOLIO 24, THREE FORKS, MONTANA, 1896.

THIS folio, by Dr. A. C. Peale, consists of 5 pages of text, a topographic sheet (scale 1:250,000), a sheet of areal geology, one of economic geology, one of structure sections, and one giving a generalized columnar section for the district.

The area covered comprises the square degree which lies between the meridians 111° and 112° and the parallels 45° and 46°, in the south-western, mountainous portion of Montana, and includes 3,354 square miles. In the extreme

southeast corner the Yellowstone National Park barely falls within the area. The folio derives its name from the valley in which the Jefferson, Gallatin and Madison rivers unite to form the Missouri. The 'Three Forks' Valley is important from an historic standpoint, as being the point which Lewis and Clark reached in July, 1805, when they named the three confluent branches of the Missouri.

The text begins with a general description of the geography and topography of the region, and then takes up the general geology. The oldest rocks in the region are the crystalline schists and gneisses, designated as of Archean age, which in pre-Cambrian time formed a land mass comprising nearly all the area included in the map. While the Algonkian beds were being deposited to the extent of from 6,000 to 12,000 feet, there was a gradual subsidence of the whole region, and shallow seas for the most part prevailed. During the Paleozoic age there were many minor oscillations of the surface, which were more frequent during Cambrian time than during the deposition of the Devonian and Carboniferous limestones. Toward the close of the Cretaceous period a general elevation began, which was accelerated after the deposition of the Laramie formation. The formation of the mountain ranges, together with the subsequent erosion, resulted in many valleys, which eventually were occupied by fresh-water lakes. These lakes attained their greatest extent in the Neocene period, lasting in all probability until the Pleistocene period was well advanced, and during their earlier stages immense bodies of wind-carried volcanic dust were deposited in their waters, and are now seen as beds of pure white dust. At the same time the dust fell upon the surrounding country, from which it was afterward washed into the lakes, forming an upper series of yellowish and rusty-colored beds. These dust showers destroyed both animal and vegetable life, and the remains carried into the lakes were buried in their deposits, where they are now found as fossil bones and opalized and silicified wood.

Under the 'Description of Rock Formations, are outlined all the formations from the Archean gneisses up through the Algonkian, Cambrian, Devonian, Carboniferous, Juratrias, Cretaceous, Eocene, Neocene and Pleistocene. The rocks of more than half of the area are of sedimentary origin, while the crystalline rocks occupy approximately 1,000 square miles, the remaining third of the area being covered with igneous material. Prominent among the latter are the andesitic breccias which form the main part of the Gallatin Range, the great porphyritic laccolite occupying the center of the Madison Range, and the basaltic plateau which lies west of the Madison Valley.

Under the heading 'Structural Geology,' after a general consideration, the vertical and horizontal movements are discussed, and the development of the lake basins is described. The arrangement of the rock masses is complex, the structure being complicated by laccolites, dikes and surface flows of igneous material. Unconformities exist, showing that areas previously raised to land surfaces and worn down have subsided, have been crossed by an advancing shore, and later have passed beneath the sea.

The lake basins are now the floors of extensive valleys separating the detached mountain ranges, which rise about 6,000 feet above their bases. As the lake deposits are at least 2,000 feet in thickness, the difference of elevation between the bottoms of the lake basins and the summits of the peaks must be at least 8,000 feet. The region was a mountainous one before the development of the lakes; but in the evolution of the existing relief, movements and erosion have both operated to accent the topographic differences.

The principal economic resources of this region are gold, silver, iron ore, copper, limestone and coal. The occurrence of coal in Devonian rocks on the north side of Jefferson Cañon is of geologic interest, although not of much economic importance. The fine pumiceous volcanic dust found in the old lake basins has been utilized to a very limited extent as a polishing material. Brick clays occur and are used to a small extent in a number of localities, especially near Bozeman. In addition to the economic resources just referred to, the sheet of economic geology has indicated upon it the localities of building stone and mineral springs.

GEOLOGIC ATLAS OF THE UNITED STATES. FOLIO 30, YELLOWSTONE NATIONAL PARK, WYOMING, 1896.

THE Yellowstone Park folio, recently issued, consists of six pages of descriptive text, three pages of illustrations, four topographic sheets (scale 1 : 125,000), and four sheets delineating the areal geology of the region.

The general descriptive text, giving a succinct narrative of the geological history and development of the Park country from the time of the earliest continental land surfaces up to and including the hydro-thermal phenomena as seen to-day, was written by Arnold Hague, geologist in charge. It is followed by an account of the sedimentary rocks from the earliest Cambrian deposits to the Tertiary conglomerates, by Walter Harvey Weed, and a detailed petrographical description of the igneous rocks, by Joseph Paxson Iddings.

The area of country covered by the Yellowstone National Park folio lies between parallels 44° and 45°, and meridians 110° and 111°. It is situated in the extreme northwest corner of Wyoming. By far the greater part of the Park is included within the area of the four atlas sheets, but a narrow strip lies to the northward in Montana, and a still narrower strip extends westward into Idaho and Montana. In the organic act establishing the Park, Congress declared that the reservation was 'dedicated and set apart as a public park and pleasure ground for the benefit and enjoyment of the people.' Owing to the marvelous display of geysers and hot springs of the region, and such remarkable physical features as the Grand Cañon and Yellowstone Lake, this folio possesses more than ordinary interest to geologists.

The central portion of the Yellowstone Park is a broad volcanic plateau with an average elevation of 8,000 feet, surrounded on nearly all sides by mountains rising from 2,000 to 4,000 feet above its general level. The continental watershed crosses the Park, separating the waters of the Atlantic from those of the Pacific, the Missouri and the Columbia, by the way of the Yellowstone and the Snake, finding their sources on this plateau.

The oldest rocks of this region are granites, gneisses and schists regarded as of Archean age. They occur in all the mountain uplifts that encircle the Park, but are unknown in the central portion. Around these ancient continental land masses there was deposited a conformable series of sandstones, limestones and shales, extending from the time of the middle Cambrian, the lowest beds exposed through the upper Cambrian, Silurian, Devonian, Carboniferous Juratrias and Cretaceous, including the Laramie sandstone. Nearly every one of these great divisions of Paleozoic and Mesozoic time is characterized by a typical fauna. With the close of the deposition of the Laramie sandstone the conformable series of sediments came to an end. The entire region was elevated above the sea, the elevation being accompanied by plication and folding of strata. This primary orographic uplift which blocked out the main ranges of the northern Rocky Mountains has been designated the post-Laramie movement.

Tertiary sedimentary rocks occupy only small areas in the Park, the greater part of the region being covered by extensive flows of lava. A heavy mass of coarse conglomerate, designated the Pinyon conglomerate, has been referred to the Eocene, and Pliocene conglomerate and coarse sands are well exposed in the escarpments of the Grand Cañon.

Volcanic energy, which has played a great part in the geological development of the country, was connected with the post-Laramie movement and followed closely upon the elevation of the mountains and the accompanying dislocation and compression of strata. The eruptive masses in forcing their way upward sought egress along lines of least resistance, or wherever strain had been greatest in the crumpled sediments. Volcanic outbursts continued on a grand scale throughout Tertiary time.

During the Eocene and Miocene periods enormous volumes of fragmental ejectamenta, largely composed of andesitic breccias, were thrown out. The Absoraka Range was almost wholly built up of volcanic material. Evidence of this long-continued action is shown in the well-preserved fossil floras of Eocene and both lower and upper Miocene age. The famous fossil forests of the Yellowstone are of Miocene age. After a period of great erosion the depressed basin lying between

the encircling ranges was transformed into the present Park Plateau by the extravasation of immense flows of rhyolite of Pliocene age. Still later the recent basalts, the last of the igneous extrusions, poured out over the rhyolite along the ridges of the plateau. A vertical section accompanies the text, showing the order of succession of the extrusive flows from the earliest outbursts to the final dying-out of eruptive energy. It is shown that long-continued currents of heated waters and acid vapors have acted as powerful agents in decomposing the igneous rocks of the plateau, and date back to Pliocene time; at least they were active before glacial ice covered the country. Hot springs, geysers and solfataras are closely associated with the rhyolite, and in fact thermal activity is confined almost exclusively to areas of this rock.

The illustrations relate mainly to the occurrence of both active and dormant geysers and hot springs, or some phase of volcanic geology. The Grand Cañon, well shown in the illustrations, is a profound gorge cut in the Pliocene rhyolite, the brilliant coloring being due to the action of thermal waters.

An Illustrated Flora of the Northern United States, Canada and the British Possessions. By NATHANIEL LORD BRITTON and HON. ADDISON BROWN. Volume II. Portulacaceæ to Menyanthaceæ. New York, Charles Scribner's Sons. Pp. 643. $3.00.

The elaborate review of the first volume of Britton and Brown's 'Illustrated Flora of the Northern United States,' which was given by Professor Conway MacMillan in SCIENCE, renders necessary only a brief notice of the second volume, which has now appeared.

Following the Engler and Prantl sequence, the first volume was made up chiefly of the monocotyledonous plants, which, compared with the other large groups of flowering plants, are probably the least attractive. In the present volume are included such large and well-known families as the Pink family, Crowfoot family, Mustard family, Rose family, Pea family, Carrot family, and the Heath family. As a whole the volume exceeds in interest and attraction the earlier one.

In running through the book a leading feature of excellence impressed upon one is that there are brought together here for the first time in a systematic manner the results of all the recent scattered special papers on our North-eastern plants. For example, the critical work done in the past few years on *Amelanchier Canadensis*, *Cardamine hirsuta*, *Ranunculus repens* and *Agrimonia Eupatoria* is here found carefully collated and systematized, full consideration being given to the conclusions of those who have done the work and whose opinions are therefore most to be depended upon.

A liberal view has been maintained regarding the delimitation of species, the work in this respect standing alone among our recent manuals. There has been a tendency among our manual writers, in case of any difficulty in the definition of specific types, to follow the antique British method of giving up any attempt at segregation and putting a number of diverse forms under one name. The results of the endeavor to give full consideration to valuable critical work is exceedingly gratifying, and will certainly serve to encourage in botanists habits of close observation on our supposedly well-known Eastern flora. No better example of judicious segregation could be cited than the separation from the old *Ranunculus repens* of three additional species, *R. septentrionalis*, *R. hispidus* and *R. macounii.*

In the matter of generic treatment this volume gives a similar impression of liberality, the limitation of genera corresponding very closely in this work with that of continental European authors. As extreme examples of the extent to which the generic segregation has been carried may be cited *Œnothera*, which is here divided into eleven genera. It is clearly a recognized principle throughout the work not merely that a genus is a group which can always be recognized by some one or more invariable technical characters fitting nicely in a key, but that it is a group of plants which resemble each other in what is perhaps best represented in English by the word *style*, and that the question of an arbitrary mark, as it were, is of secondary, not of primary importance.

The drawings, for which the book is most likely to be criticised by botanists of critical

training, are usually excellent, and to the ordinary student, for whose guidance they were evidently more especially intended, they must always prove valuable. The drawings of the violets, for example, are excellent and helpful representations of the different species of that group. In the case of the genus *Myriophyllum* in which the drawings have less of sharpness and more of the character of sketches, the species, which everyone has had difficulty in understanding from mere descriptions, can be readily recognized from the drawings.

Probably the principal fault in the general make-up of the work lies in the separation of the Latin and English indexes, a system which if carried through the third volume would sometimes make it necessary for one unfamiliar with botanical names to look in six different indexes in order to find a particular plant. It is to be hoped that the third volume will contain a single combined Latin and English index to all three volumes.

The impression is strengthened by this second volume that this work marks an epoch in the development of systematic botany in America, combining, as it does, the best of the new ideas which have been current in this country for twenty years and which had their source in the new method of systematic research in which the younger generation had been educated, based on the Darwinian ideas of genetic development.

F. V. COVILLE.

SCIENTIFIC JOURNALS.

TERRESTRIAL MAGNETISM FOR JUNE.

THE first article, by Dr. J. A. Fleming, on 'The Earth a Great Magnet,' gives a popular exposition of the principal phenomena of the earth's magnetism. For many years it has been the custom to have a popular experimental or illustrated lecture delivered during the meeting of the British Association for the Advancement of Science, addressed especially to the artisans of the town in which the meeting takes place. This article gives the text of the discourse delivered by the author before the workingmen of Liverpool at the last meeting of the British Association. Dr. Fleming's most admirable lecture was profusely illustrated by experiments, and was presented before a very large audience in the Picton Hall. It appears in *Terrestrial Magnetism* in full for the first time.

Professor McAdie reviews and summarizes the present state of our knowledge with regard to 'The Electrification of the Atmosphere,' as set forth in the recent publications of Chree, Elster, Geitel and Schuster. The author thinks that there are good grounds for believing that the twentieth century will number among its triumphs a complete electrical survey of the atmosphere. He regards the question as to the relation between the magnetic elements and the atmospheric electric currents as the coming one.

Mr. Littlehales gives an abstract of his recent researches with respect to the establishment of 'Secular Variation Expressions of the Magnetic Inclination.' This investigation is preparatory to a future article which will give the secular change in the direction of a freely suspended magnetic needle at each of twenty-two stations distributed over the globe.

Dr. Bauer, in the next article, 'A Remarkable Law,' presents formulæ giving the diurnal range of the magnetic declination and inclination as simple functions of the magnetic inclination. The formulæ were first found empirically and then deduced theoretically by assuming that the component of the deflecting force producing the angular deflection of the needle from its mean position is inversely proportional to the force exerted on the needle by the earth's permanent magnetism. The formulæ would imply that the lines of equal magnetic inclination represent closely the lines of equal diurnal range. The author finds that the same functions hold with regard to some of the secular and distribution phenomena of the earth's magnetism.

In 'Letters to Editor' is a communication from Professor Hellman regarding Stevins's 'ΛΙΜΕΝΥΡΕΤΙΚΗ;' another from Dr. van Bemmelen discussing the non-cylic phenomena of the diurnal variations, and a third from Drs. von Rijckevorsel and van Bemmelen giving the results of their magnetic observations on the Rigi, made in 1895 and 1896.

THE AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

THE meetings of the American Association for the Advancement of Science at Detroit next week and of the British Association at Toronto on the following week are events of more than ordinary moment. The visit of the British Association to Montreal in 1884 gave a considerable impulse to science in America. The meeting of our own Association in that year was attended by three hundred British men of science, the total attendance, 1249, being the largest in its history. In the thirteen years that have since elapsed science in America has made a great forward movement. The scientific research accomplished at our universities now surpasses that of the British universities; the work done under our government is greater than in any other country; our scientific journals have doubled in number and increased in influence. If our Association has scarcely kept abreast of the great progress of science, this is the proper time to give it a due place in the scientific economy.

It is certainly the duty as well as the privilege of every American man of science to try to attend the meetings at Detroit and

Toronto. The places and times have been arranged so that this can be done conveniently. The scientific programs and social arrangements for both meetings promise ample reward for those who are able to be present. We must not fail to give British men of science a cordial welcome, and we have much to learn from their meeting. Our own Association deserves support. Every motive of public spirit and self-interest should lead us to make the meeting at Detroit worthy of the present position of science in America and a stepping-stone in its progress.

We do not at all sympathize with the idea sometimes expressed that National Associations for the Advancement of Science have outlived their usefulness. There is nothing more typical of modern social conditions than combinations and trade-unions. Human development depends less than formerly on natural selection of the individual and more on competition between groups. It will fare ill with men of science if they cannot unite to maintain and forward their common interests. With them not only selfish instincts of self-preservation are concerned, but also moral sentiments, for they believe that the interests of science are in large measure conterminous with the interests of civilization.

The objects of the American Association for the Advancement of Science "by periodical and migratory meetings, to promote intercourse between those who are cultivating science in different parts of America, to give a stronger and more general impulse and more systematic direction to scientific research, and to procure for the labors of scientific men increased facilities and a wider usefulness," are as valid and as important now as they were when the constitution was adopted fifty years ago. Indeed, as the magnitude of the interests increases, the need of caring for them becomes more urgent. With the growth of specialization and the scattering of men of science over the whole area of America, the need of cultivating intercourse between them becomes more pressing. The greater popular interest in science requires direction into proper channels. As science grows, it needs more workers and more money. The workers must be secured from students at school and college, the money from private gifts and from the State. The magnitude of scientific work is now such that in many cases it can only be accomplished by united effort continuing for years. Witness what the Royal Society has accomplished in inaugurating international cooperation in the cataloguing of scientific literature; the Zoologische Gesellschaft in the publication of 'Das Tierreich,' the British Association in the work of its committees. The American Association should not only maintain its present position, but should make itself a still more important factor in the advancement of science.

It must not be forgotten that as the environment alters, the organization that will survive must accommodate itself to the new conditions. Science in America is very different to-day from what it was fifty years ago. There is reason to doubt whether the Association has in like measure enlarged its range and increased the nicety of its adjustments. Methods suitable to a small gath-

ering from a limited area, representing sciences undeveloped and undifferentiated, may have been outgrown.

It seems evident that the permanent organization of the Association, both at and between the meetings, should be strengthened. Even a congress or legislature whose professed object it is to legislate must leave the real work to committees. The democratic character of a scientific association is sufficiently guarded by the election of representatives who will carefully consider and decide questions of policy. It is, indeed, possible that the present Council of the Association is too cumbersome. Then there is need of a strong interim organization, and we think that this should be extended to the sections. A permanent secretary and a committee or council for each section would give greater continuity and efficiency.

It is not possible to divide the field of science into nine sections, each homogeneous and independent of the others. Section A is for mathematics and astronomy, but there are portions of astronomy less closely related to mathematics than are portions of physics, of chemistry and of engineering. The International Congress of Mathematicians meeting this summer will be divided into six sections. On the other hand, there are subjects that would naturally fall in or between two or more sections, and others that would include several sections. Modern science is marked by great specialization, and this itself gives rise to nearly all possible combinations of the sciences and leads us back to the ultimate unity of science.

The solution for the Association seems to be that there should be, on the one hand, sub-sections—consisting perhaps of societies with separate organizations—for the reading and discussion of papers, important only for a limited group of students; and, on the other hand, joint meetings of two or more sections or of the whole Association for the consideration of subjects of general scientific interest, and to promote the organization and advancement of science as a whole.

For example, during the past year two of the most important contributions made to the theory of evolution for a long time have come from America. These are that individual variations set the line of organic evolution and that variations and heredity, respectively, have been confused by attributing the former to the environment and the latter to the organism. These advances have been proposed by a psychologist, a zoologist, a botanist and a geologist. They are not yet acknowledged nor understood by men of science abroad, and would have been a suitable subject for a session of the whole or a large part of the Association.

Taking next an example of desirable specialization, it may be noted that there meet during the Christmas holidays four societies for which there are no places in the Association; these are the American Physiological Society, The Association of American Anatomists, The Society of Morphologists and The American Psychological Association. Each of these societies is composed exclusively of those devoted to research in the sciences represented. At the last meetings an aggregate of over 100 papers was presented, representing one-half

as many papers as are annually read before the Association. It is evident that the Association cannot represent the whole of American science while such important developments are ignored. Only a small percentage of the members of these societies are fellows of the Association.

Indeed, we must admit that a large proportion of those most actively engaged in advancing science in America do not attend the annual meetings, and many are not even fellows of the Association. We may appeal to the public spirit of these men of science and probably with success. It would, however, be far better to make the meetings so fruitful that each would like to attend, and, if possible, to give those unable to attend some return for membership in addition to the annual volume of proceedings. Election as fellow should be an honor that no one would decline. The fellows should not be elected exclusively from the members, but those who are doing the most for the advancement of science in America should be the fellows of the Association. It would probably be desirable to limit the number of fellows to one thousand and to fill vacancies each year as they occur. As soon as the fellows of the Association were acknowledged to be the thousand leading men of science in America, election would be an honor only less in degree than election to membership in the National Academy of Sciences. In this case an added interest would be given to the annual meetings. With the National Academy as the 'upper house' and the American Association the 'lower house' of American science a great improvement in organization would be effected. It would be a natural courtesy for the Academy to elect its members from the Association and for the Association to elect its President from the Academy. We may view with great satisfaction the fact that the President of the National Academy is this year President of the Association.

In conclusion, we may once more urge the importance of attending the Detroit meeting of the Association and of proceeding thence to Toronto. Those taking part in these meetings will receive a stimulus in scientific activity, and by making the meetings noteworthy will contribute greatly to the advancement of science in America. Questions affecting the future of the Association will be considered at Detroit, and arrangements will be made for adequately celebrating the fiftieth anniversary of the Association. There is no doubt but that during the next fifty years science will be the leading factor in the progress of the world, and probably more depends on America than on any other country. The American Association for the Advancement of Science has great opportunities and great responsibilities.

THE INTERNATIONAL CATALOGUE OF SCIENTIFIC LITERATURE.

The International Bibliographical Conference held in London, July 14–17, 1896, was the most important step ever taken toward international cooperation in scientific and bibliographical work. This account of the meeting is derived, unfortunately, not from personal knowledge, as I was not present. I have had, to aid me in its preparation, the two official publications

of the Conference, the so-called Acta and a verbatim report of the proceedings issued by the Royal Society, as well as information derived from the United States delegates, and the official correspondence of the Smithsonian Institution.

Before taking up the Conference itself, it might be well to consider briefly the history of the movement toward an international catalogue of scientific works. It is no small satisfaction to us that the incentive to this work came from America. Professor Joseph Henry first conceived a plan for a scientific bibliography in 1854, and when he sought the cooperation of the British Association for the Advancement of Science, the subject was referred to a committee consisting of Fellows of the Royal Society who approved the suggestion. Ten years later the Royal Society aided by government grant undertook the publication of a catalogue of scientific papers since 1800, 11 volumes of which have now appeared. In the preface to the first volume we read: "The present undertaking may be said to have originated in a communication from Dr. Joseph Henry, Secretary of the Smithsonian Institution, to the meeting of the British Association at Glasgow in 1855, suggesting the formation of a catalogue of philosophical memoirs."*

*"A communication from Professor Henry, of Washington, having been read, containing a proposal for the publication of a Catalogue of Philosophical Memoirs scattered throughout the Transactions of Societies in Europe and America, with the offer of cooperation on the part of the Smithsonian Institution, to the extent of preparing and publishing, in accordance with the general plan which might be adopted by the British Association, a Catalogue of all the American Memoirs on Physical Science, the Committee approve of the suggestion and recommend that Mr. Cayley, Mr. Grant and Professor Stokes, be appointed a committee to consider the best system of arrangement, and to report thereon to the Council." (Rept. of the 25th meeting of the British Association for the Advancement of Science, held at Glasgow in September, 1855, p. LXVI.)

"This index of all the physical papers in the transactions of learned societies and in the scientific periodicals resulted from a letter addressed to the British Association in 1855, by the Secretary of this Institution, setting forth the advantages to science of such a work. The matter was referred to a committee of the Association, reported favorably upon, and recommended for execution to the Royal Society." (Smithsonian Report for 1867, p. 58.)

In March, 1894, the Royal Society issued a circular to learned societies throughout the world, which called attention to the fact that the catalogue of scientific papers was limited to periodical scientific literature, taking no account of monographs and independent books and that titles were arranged solely by authors' names. Further, that the catalogue was confessedly incomplete. The development of scientific literature had been so great and the need for a subject catalogue so apparent that the President and Council of the Royal Society appointed a committee "to inquire into and report upon the feasibility of such a Catalogue being compiled through International Cooperation." A circular embodying these statements was sent to learned societies in correspondence with the Royal Society and elicited very general and favorable response. At the same time the following letter was addressed to the Smithsonian Institution:

"MY DEAR PROFESSOR LANGLEY: The Smithsonian Institution is, on historical grounds, so closely connected with the efforts of the Royal Society in cataloguing scientific papers that I am directed to add to the circular letter herewith sent, a few words expressing the hope of the Committee of the Royal Society which has the matter in hand that they may have, in a special way, the assistance of your valuable body in coming to a decision on so important a question. Believe me, yours very truly,

[Signed] M. FOSTER,
Sec. R. S."

The matter occasioned much discussion both in this country and abroad. The circular was published in full in SCIENCE,* and there appeared in the same number a report of a committee of the Faculty of Harvard University to the University Council expressing its sympathy, making some suggestions and recommending that the corporation of Harvard University contribute a certain sum toward carrying out the enterprise.

Professor Henry A. Todd,† of Columbia University, made some suggestions in regard to a card catalogue of scientific literature with annotations. He proposed that the Smithsonian Institution should assume the leaderehip in America, and that publishers should be asked to coöperate.

Mr. W J McGee‡ discussed certain of the practical sides of the question, and announced that the Geological Society of America had concurred in the report of the Harvard University Council. The Franklin Institute, of Philadelphia, also expressed itself favorably.§

Doctor G. Brown Goode|| laid down a most careful plan of operations. He held that the catalogue should be international in name and scope, should be exhaustive within its own limits, and that it should be published in book form, as a card catalogue would, in his opinion, be too bulky. He also suggested a broad classification of science which, it may be said by way of anticipation, included economic science, mechanical science and engineering, philology and institutional history, all of which were excluded by the Conference.

Numerous other bodies responded favorably and many articles were written on the subject.

The next step in the matter was taken when the Royal Society issued a circular in August, 1895, containing a report made to the President and Council in July, 1895, by the Special Committee. This circular stated that more than one hundred replies had been made to the original circular and that in no single instance was any doubt expressed as to the value of the work proposed. The cordial letter of the Secretary of the Smithsonian Institution and the replies received from the United States were especially dwelt upon, and the holding of an international conference as a first step in the matter was recommended by many Societies.

Accordingly, on August 15, 1895, the Secretary of the Royal Society addressed a letter to the Marquis of Salisbury, Premier and H. M. Minister for Foreign Affairs, in which he reviewed the matter and pointed out the advisability of a conference in London looking to international cooperation. He suggested that such a conference be called by the British government and that certain governments named should be invited.

In pursuance of this suggestion, the Department of State at Washington (and it may be assumed that a similar course was followed with regard to other countries) received from the British Ambassador, in October, 1895, a copy of the letter of the Royal Society, with the expression, on the part of Lord Salisbury, of the hope that the United States government would be represented at the conference. This matter was referred by the Secretary of State to the Secretary of the Smithsonian Institution, who recommended that the United States government should take part and suggested that Dr. John S. Billings and Professor Simon Newcomb should serve as delegates for the United States, a recommen-

|| SCIENCE, N. S., Vol. I., p. 433 'Ideal Index of Scientific Literature.'

dation which was adopted. The conference was formally held at London, July 14–17, 1896.

With this brief introduction I will now give: (1) a list of the governments represented by delegates; (2) a condensed account of such portions of the debates as would seem to be of especial bibliographical and scientific interest; (3) for the sake of clearness, a recapitulation of all of the resolutions agreed to with the exception of such as related purely to matters of detail concerning the holding of meetings, and (4) the report of the United States delegates, together with official documents relating thereto.

The following delegates attended:

Austria.—Prof. Ernst Mach (Mitglied der Kaiserlichen Akademie der Wissenschaften, Vienna). Prof. Edmund Weiss (Mitglied der Kaiserlichen Akademie der Wissenschaften, Vienna).

Belgium.—M. H. La Fontaine (Membre de l'Institut International de Bibliographie, Brussels). M. Paul Otlet (Membre de l'Institut International de Bibliographie). M. de Wulf (Membre de l'Institut International de Bibliographie).

Denmark.—Prof. Christiansen (Universitet, Copenhagen).

France.—Prof. G. Darboux (Membre de l' Institut de France). Dr. J. Deniker (Bibliothécaire, Muséum d' Histoire Naturelle, Paris).

Germany.—Prof. Walther Dyck (Mitglied der K. Bay. Akad. der Wiss. zu München). Prof. Dziatzko (Direktor der Universitäts Bibliothek, Göttingen). Prof. Van't Hoff (Mitglied der K. P. Akademie der Wissenchaften zu Berlin). Prof. Möbius (Mitglied der K. P. Akademie der Wissenschaften zu Berlin). Prof. Schwalbe (Direktor, Berlin).

Greece.—M. Avierinos M. Averoff (Greek Consul at Edinburgh).

Hungary.—Prof. August Heller (Librarian, Ungarische Akademie, Buda-Pesth). Dr. Theodore Duka (Membre Academie Hongroise des Sciences, Buda-Pesth).

Italy.—General Annibale Ferrero (Italian Ambassador in London).

Japan.—Assistant Prof. Hantaro Nagaoka (University, Tokio). Assistant Professor Gakutaro Osawa (Medical College, Tokio).

Mexico.—Senor Don Francisco del Paso Y Troncoso.

Netherlands.—Prof. D. J. Korteweg (Universiteit, Amsterdam).

Norway.—Dr. Jorgen Brunchörst (Secretary, Bergen Museum).

Sweden.—Dr. E. W. Dahlgren (Librarian, Kongl, Svenska Vetenskaps Akademie, Stockholm).

Switzerland.—M. C. D. Bourcart (Swiss Minister in London). Prof. Dr. F. A. Forel (President du Comité Central de la Société Helvétique des Sciences Naturelles).

United Kingdom.—Representing the government: Right Hon. Sir John E. Gorst, Q. C., M. P. (Vice-President of the Committee of Council on Education). Representing the Royal Society of London: Prof. Michael Foster (Sec. R. S.). Prof. H. E. Armstrong, F. R. S. Mr. J. Norman Lockyer, C. B., F. R. S. Dr. Ludwig Mond, F. R. S. Prof. A. W. Rücker, F. R. S.

United States.—Dr. John S. Billings (U. S. Army). Prof. Simon Newcomb, For. Mem. R. S. (U. S. Nautical Almanac Office).

Canada.—The Hon. Sir Donald A. Smith, G.C.M.G. (High Commissioner for Canada).

Cape Colony.—Roland Trimen, Esq., F.R.S. Dr. David Gill, C.B., F.R.S.

India.—Lieut.-General Richard Strachey, R.E., F.R.S.

Natal.—Walter Peace, Esq., C.M.G. (the Agent-General for Natal).

New South Wales.—Prof. Liversidge, F.R.S.

New Zealand.—The Hon. W. P. Reeves (Agent-General for New Zealand).

Queensland.—Chas. S. Dicken, Esq., C.M.G. (Acting Agent-General for Queensland).

The verbatim report of the debates, which accompanied the introduction of the resolutions, is much too voluminous to give even in abstract, but it would seem worth while at least to epitomize a few of the more salient points in the discussion which took place.

The attitude of the Royal Society toward the whole subject was sketched at the opening of the meeting by Professor Armstrong. The Society, he said, had felt for a number of years that in publishing a catalogue of scientific papers "it was not doing nearly enough to supply the needs of scientific workers; that the production of a catalogue arranged only according to the authors' names was altogether insufficient, and that it was essential that much more should be done, and that work should be

done much more quickly. * * * The great object before us is to produce a catalogue available for use by scientific investigators throughout the world. It is not a mere bibliographical work that we are seeking to perfect."

An interesting discussion took place on the motion of Professor Michael Foster, "that each delegate should have a vote in the deciding of questions before the Conference." Professor Simon Newcomb stated that it was not inappropriate that he should second the resolution, inasmuch as the United States would apparently be among the nations placed at the greatest disadvantage by this method of voting. Professor G. Darboux, a member of the Institute of France, representing the French government, said that he had sought instructions upon this subject, but had not received any; that in congresses of this sort votes were usually taken by nations and that if the other method was to have prevailed it should have been made known, so that more delegates could have been sent. General Ferrero, the Italian Ambassador at London, representing Italy, agreed that the observations of Professor Darboux were most important. He added, however, that with regard to questions which really are matters of science pure and simple it was the opinion of the delegates, not of nations, which was desired; while questions which were without the realm of science could readily be left to the governments to settle. In the question of classification, for example, there was no question of national interest; it was a question of science pure and simple.

Professor Möbius, representing Germany, said that the German delegates were sent by the German government or by learned societies to assist in the discussions, and to represent either the government or societies in order that they might determine in what manner they should participate in the work. He held, therefore, that they should take part as individuals, which was agreed to by Professor Edmund Weiss, representing Austria.

Professor Darboux accepted this explanation, remarking that the matter was cleared up in his mind that the meeting was not a diplomatic conference, but a congress of scholars charged to examine into the best methods of accomplishing a certain proposition, and that the final questions of finance and participation were to be referred to the respective governments. The motion was then unanimously agreed to.

Professor Armstrong moved "that it is desirable to compile and publish, by means of some international organization, a complete catalogue of scientific literature arranged according both to authors' names and to subject-matter." This was adopted, with the last clause reversed, to read "both to subject-matter and to authors' names," in accordance with the suggestion of Professor Forel, representing Switzerland. M. Otlet, one of the Belgian representatives, took the introduction of this resolution as the occasion for the presentation of a note on behalf of the Belgian delegates. This note was in the nature of a discussion of the entire subject of international bibliographical work, with special reference to the establishment of an office at Brussels some years previous. The introduction of this note occasioned some discussion with regard to the decimal system of classification. Opinions against its practicability were expressed by Professor Schwalbe, of Germany; Professor Heller, of Hungary; Professor Dziatzako, of Germany, and Professor Darboux. The discussion, however, was brought to a close by the Italian representative calling attention to the fact that it did not bear directly on the resolution before the Congress.

The next resolution which occasioned

discussion read as follows: "That the administration of such a catalogue be entrusted to a representative body hereinafter called the International Council, the members of which shall be chosen as hereinafter provided by the several countries (hereinafter spoken of as the constituent countries) who shall declare their adhesion to the project."

Professor Korteweg, representing Netherlands, proposed an amendment, which was, in substance, that the preparation of the subject catalogue should be entrusted to an international commission representing the different branches of science and that this commission should nominate the International Council. He argued that different branches of science had different needs; that under this proposal it is possible that certain branches of science would not be represented at all, or at best very unequally. Professor Armstrong suggested that it would be well to settle the question in brief, leaving the further details until afterwards. Lieutenant-General Strachey, representing India, pointed out certain other difficulties in the wording of this resolution. Dr. J. S. Billings, of the United States of America, stated that the point raised by Professor Korteweg was so important that he should prefer to see it written down and be able to consider it. Professor Korteweg then withdrew his amendment. The form suggested by Dr. Billings was objected to by Professor Foster, on the ground that it did not provide that representatives of the several countries should be on this Council, to which Dr. Billings replied: "We are not trying so much to get representation of the countries in the first place. It would be a representation of the different branches of science. The countries come in as secondary to the sciences in this representative body." After some further discussion, the resolution, as amended by Dr. Billings, was adopted.

The next resolution read was: "That the final editing and the publication of the catalogue be entrusted to an organization hereinafter called the Central International Bureau, under the direction of the International Council." This resolution, Professor Armstrong explained, would only pledge the Conference to the organization of a central office and in no way preclude the establishment of branch offices. The discussion of this resolution, in connection with the following one, brought out the question from Professor Schwalbe as to what should be done to catalogue the literature of those countries which did not contribute or failed to adhere to the scheme; to which Professor Armstrong replied that in this event he thought the central office should carry out the work. Professor Dyck, representing Germany, thought that there should be a central office, but he raised the question as to whether the subordinate councils should not be considered by sciences instead of by countries. Professor Forel pronounced most emphatically for the arrangement by nationalities. M. Otlet, representing Belgium, was strongly in favor of a division into the sciences instead of by nationalities. He argued, first, that it would be very difficult for the smaller countries to organize a commission embracing all the sciences, and, secondly, that the various sciences were already so well organized, through national and international societies, that if the matter were arranged in this way these organizations would prove powerful auxiliaries. M. Darboux was strongly in favor of an arrangement by nations, pointing out that if the matter were left to some special organizations great difficulties would arise, as the limits between the sciences were hardly decided; "if, for example," he said, "you separate physics and chemistry you run the risk of entirely sacrificing the region intermediate between the two sciences, which is,

moreover, precisely the one in which the most interesting discoveries are being made." Professor Schwalbe gave as a further reason for adhering to nations that it would be easier for a national commission to get the material and, moreover, that in countries in which different languages were employed it would be easier to arrange for classifying the material in that way. The resolution was unanimously agreed to.

The next resolution proposed read as follows: "That any constituent country which shall declare its willingness to undertake the task shall be entrusted with the duty of collecting, provisionally classifying, and transmitting to the Central Office, in accordance with the rules laid down by the International Council, all the entries belonging to the scientific literature of that country, the work of the Central Bureau being in such cases limited to revising and incorporating into the catalogue the entries so received."

Dr. John S. Billings moved an amendment to have the word 'constituent' stricken out and have it read 'any country.'

Dr. Ludwig Mond proposed that the words "the work of the Central Bureau being, in such cases, limited to revising and incorporating into the catalogue the entries so received" be omitted. This motion, as amended, was unanimously agreed to.

The next resolution was: "That, in the classification according to subject-matter, regard shall be had not only to the title (of a paper or book), but also to the nature of the contents." Professor Armstrong explained that this meant that papers would have to be read and studied in order that proper indexes might be prepared. He said, further, that it was his belief that in the future it would be necessary to insist that the author of every paper supply with his paper the material for a subject-index, which, of course, could be revised at the headquarters and subsequently at the Central Office. Dr. Billings moved that the word 'indexing' be substituted for 'classification,' which word he thought had been used wrongly. M. Deniker, representing France, pointed out that, while it was a comparatively simple matter to furnish titles, it was extremely difficult to analyze the contents. He asserted that a single article on zoology describing new species might require two hundred cards. M. Darboux seconded this observation. It is very necessary to zoology, he said, to know whether families or species were to be recorded. If the latter the number of cards would reach immense proportions, and he thought the success of the catalogue depended upon the solution of this question.

The next resolution was: "That the catalogue shall comprise all published original contributions to science, as hereinafter defined, whether appearing in periodicals or in the publications of societies, or as independent pamphlets, memoirs or books." Professor Armstrong pointed out that the object of this resolution was to include in the catalogue of the future all original scientific literature. He stated that in the past it had been the habit of the Royal Society to take note only of periodicals and of the publications of societies, so that the whole of Darwin's work which had not appeared in the publications of a society had been omitted, which was obviously absurd. Professor Newcomb objected to the words 'to science as hereinafter defined,' and suggested, 'to the branches of science hereinafter mentioned,' which suggestion was accepted. Professor Dziatzko pointed out a difficulty. Periodicals, he said, can be procured through exchange, but the matter of books is a much more serious problem, as in the larger countries it would be difficult to get all the titles of books, not to speak of copies of the books themselves; in England, the United States and France this matter

could be arranged through the copyright, but in Germany the copyright had been left to the different states of the Empire and the regulations were different. In Saxony, which included the great publishing town of Leipzig, copies of books were not required to be furnished, and the same difficulty existed in Switzerland. Professor Schwalbe thought that absolute completeness would probably be impossible, mentioning by the way that even the daily newspapers occasionally contain articles of high value which would have to be considered. Professor Mach pointed out that in Austria it was compulsory to register and deposit books, and he expressed the hope that if the Congress came to a successful issue the various governments would enact laws making the deposit of books compulsory. Professor Korteweg suggested that one difficulty would be to make the proper distinction between original works and those which had only a pedagogical value. The elementary book must be omitted, yet there were among such books many that deserved a place. At all events, he thought it desirable to state the principle that pedagogical books on popular science should be excluded. Professor Newcomb thought that the necessary omissions would not materially detract from the value of the catalogue. "Naturally," he said, "every author, if he knows that this is the only way of making his work known, will send a copy to the Bureau, or take some means of making the Bureau aware of his work." Professor Armstrong thought that there would be no difficulty, because the proposed catalogue would serve as the best possible advertisement for the books. This resolution was unanimously agreed to.

The next resolution was a most important one, being designed to bring out the distinction between pure and applied science. As introduced it reads as follows: "That a contribution to science for the purposes of the catalogue be considered to mean a contribution to any of the following sciences: mathematics, astronomy, physics, chemistry, geology, zoology, botany, physiology and anthropology, to the exclusion of what are sometimes called the applied sciences, the limits of the several sciences to be determined hereafter." Professor Schwalbe raised the question whether geography was to be considered one of the natural sciences. In Germany, he said, it was regarded not simply as an auxiliary to natural science, but as a science which of itself had relations to the whole series of natural phenomena, being related to anthropology and astronomy as well as to land surveys. He thought that geography was as much a science as chemistry or physics, and that even anthropology belonged to geography, except that portion of it which was related to anatomy. He was himself of the opinion that anthropology and geography had best be treated together. Professor Heller proposed, as a title, the 'physics of the earth,' stating that geography, meteorology and all sciences which had to do with the knowledge of the earth could be included under this title, excepting physics and astronomy. Mineralogy, he thought, could be treated as a separate science, while geography appeared to be only a portion of the science of the physics of the earth. Professor Christiansen, of Denmark, thought that it would be very difficult to define the different sciences, and that it would be best to take simply mathematics, astronomy, chemistry and botany. Professor Armstrong called attention to the fact that the question under discussion really was whether applied science was to be included. Professor Forel suggested that the phrase be simply 'physical and natural sciences, mathematics,' etc., which was agreed to by Professor Möbius, who remarked that historical studies would have to be omitted. Dr. Billings suggested

that the resolution should run: "mathematics, astronomy, physics, chemistry, geology and the biological sciences, including zoology, botany, morphology, physiology, anthropology, ethnology," etc. Dr. Billings did not think the term 'applied science' clear. In a sense astronomy is applied mathematics. He thought that some phraseology should be employed which indicates the application of sciences to professional and commercial purposes. He also called attention to statistics, which might be considered from a scientific point of view, and thought it well that the broader term biology should be introduced, instead of physiology or anthropology. Professor Möbius, after some further discussion of this resolution, pointed out that the term biology did not have the broad significance in Germany which Dr. Billings ascribed to it. The discussion of this resolution was adjourned for the day.

When the Conference met on the following day, July 15th, the mover of the resolution concerning the scope of the catalogue withdrew it by permission for the purpose of amendment. The discussion of this subject, which is really of much significance to scientific men, continued, and it was apparent that no conclusion could be reached. There seemed to be a tendency to use the words natural and physical sciences, thus leaving the whole matter indefinite. This Dr. Billings very strongly opposed on the ground that the statement as to the general scope of the catalogue should be in such form as to be perfectly clear to all scientific men. But it was evident that the question could not yet be settled, and it was finally decided to refer the terms of the resolution to a committee consisting of Professor Armstrong, Dr. Billings, Professors Möbius, Korteweg and Schwalbe.

The next matter that was of interest was a resolution which read: "That in judging whether a publication is to be considered as a contribution to science, suitable for entry in the catalogue, regard shall be had to its contents, irrespective of the channel through which it is published." It is interesting to note that there was no dissent from this proposition, and that the importance of it was emphasized by the German delegates, several of whom pointed out the fact that trade journals, as, for instance, that devoted to the beet sugar industry, or even the *Allgemeine Zeitung*, often contain scientific articles of great value.

The next resolution, which was one of great importance, read: "That the double system of authors' names and subject-matter being always maintained, the Central Bureau shall issue the catalogue in the form of 'slips or cards,' the details of the cards to be hereafter determined and the issue to take place as promptly as possible. Cards corresponding to any one or more of the branches of science, or to sections of such branches, shall be supplied separately upon such demand." Dr. Ludwig Mond thought that the issuing of cards should be at the discretion of the International Council. Dr. Billings preferred that they should be at the discretion of the Central Bureau. He pointed out that it was a purely commercial detail, and that its advisability depended upon the number of subscriptions received in advance. He hardly thought that a double system was necessary in case of the cards. There was a lengthy discussion over various forms of amendment, that of Dr. Billings being finally carried by the rather close vote of 18 to 14.

The next resolution related to the issue of a catalogue in book form and this, too, being modified, was passed, as follows: "That the Central Bureau shall also issue the catalogue in book form from time to time, the titles being classified according to the rules to be hereafter determined; that the issue in the book form

shall be in parts corresponding to the several branches of science, the several parts being supplied separately, at the discretion and under the direction of the Central Bureau."

The President of the Conference next invited expressions of opinion as to where the Central Bureau should be situated. After a brief address, in which he referred to the fact that the International Bureau of Weights and Measures was established at Paris and the International Bureau of Geodesy at Potsdam, General Ferrero, representing Italy, proposed that the Central Bureau should be established at London. M. Darboux stated, on behalf of the French delegates, that they had been charged by their country to make the same proposition. Professor Möbius made a similar statement on behalf of the German delegates, and Professor Heller for Hungary, Professor Weiss for Austria, Professor Newcomb for the United States; and the representatives of Belgium, Switzerland, Denmark, Sweden and Netherlands agreeing, the resolution to have London as a central office was carried by acclamation. Professor Foster, Secretary of the Royal Society, acknowledged the extremely sympathetic manner in which this resolution had been proposed and carried.

The President of the Conference expressed his thanks on behalf of the British government for the unanimous action of the Conference, assuring them that nothing would be wanting in his country in the endeavor to make this international work a success.

He then invited an expression of opinion as to the constitution of the Council. Professor Foster remarked that there were several ways of electing a council. One was that there should be an appointment of international committees corresponding with the various branches of science and that these international committees should nominate the council. Another plan was that each nation should nominate its members for the council directly. The German delegates stated that they had been directed, by the bodies they represented, to refer back to them the choice of persons for the international bureau. Professor Schwalbe agreed to this view, asserting that the right should be reserved to each government to name the persons who would represent it in carrying on the enterprise. Dr. Duka, representing Hungary, thought that this was a matter to be referred to the respective governments. Various delegates followed this idea, suggesting a postponement of the whole subject, but Professor Newcomb pointed out that inasmuch as this Conference had decided to appoint an international council it could not adjourn without indicating in some way the steps to be taken in the formation of the council. As a tentative proposition he, therefore, proposed the following resolution: "The International Council shall consist, in the first place, of members, one of whom shall be appointed by the government of each country taking part in the preparation of the catalogue. The Council as thus formed shall have power to choose such additional members as it shall deem necessary for the efficiency of its organization." Dr. Billings noted a difficulty in the use of the word government. He said it might very well happen in the United States that the government might have nothing to do with the preparation of the catalogue; that it might come under such bodies as the National Academy of Sciences or the Smithsonian Institution, which could not be said to be the government of the United States. General Ferrero agreed with the suggestion of Dr. Billings, thinking that it might be better for the enterprise if the choice of the delegates were left to some scientific body. M. Darboux thought that

everybody would agree that the nomination should be by the government. Professor Dziatzko proposed that the Conference should appoint a provisional committee, which should enter into communication with various governments and learned societies and thus prepare for a second conference which would settle all details. General Ferrero thought that the Royal Society could itself take the place of the provisional committee suggested by Professor Newcomb, but no definite agreement was arrived at on this point, and the Conference adjourned for the day.

On Thursday, July 16th, the Conference again assembled, and the special order was the report of the committee for the purpose of considering a resolution to indicate the nature of the subjects to be admitted to the catalogue. This committee reported as follows: "That a contribution to science for the purpose of the catalogue be considered to mean a contribution to the mathematical, physical, or natural sciences, such as, for example, mathematics, astronomy, physics, chemistry, geology, mineralogy, zoology, anatomy, botany, physiology, general and experimental pathology, experimental psychology, and anthropology, to the exclusion of what are sometimes called the applied sciences, the limits of the several sciences to be determined hereafter." Professor Möbius called attention to the fact that experimental psychology was known in Germany as psycho-physics, and it was agreed to insert that word in the German text. Professor Forel and the Italian Ambassador favored the inserting of mathematical and physical geography, which was agreed to. M. Otlet suggested the insertion of paleontology, but several members insisted that this was included under zoology.

This matter, which threatened to cause considerable trouble being disposed of, the resolution of Professor Newcomb respecting the constitution of an International Council was taken up, and with the permission of the Conference his resolution was withdrawn in order that another one, which had received fuller consideration, should be admitted. Professor Foster said that he understood it to be the view of the Conference to remit the question to the Royal Society. He said that while the Society would be very proud to accept any duty which might be imposed upon them they would shrink from any executive power in connection with the matter. It had been suggested that this organizing committee of the Royal Society should report to a future meeting of the Conference, but this was objected to by several persons on the ground that when the Conference was adjourned it ceased to be, so that a future Conference was suggested. One of the longest discussions of the entire meeting now followed, but it related largely to questions of diplomacy and policy and may well be omitted here. After many amendments the resolution read: "That the Royal Society be requested to form a committee to settle the questions relating to the catalogue referred to it by the Conference, or remaining undecided at the close of the present sittings of Conference, and to report thereon to the governments concerned."

The next important matter was the introduction of the following resolution: "That whatever system of classification be ultimately adopted for the catalogue it is impossible to accept the Dewey system *en bloc.*" By way of explanation of this resolution Professor Armstrong said that he had put it in this form because the International Conference of Bibliography at Brussels had accepted the Dewey system and because it was so widely used in certain libraries. The Royal Society, while not denying the merits of the system for the librarian's use, held that it was impossible to accept it for the purpose of scientific workers. M. Otlet favored the Dewey system. Professor

Heller thought it not practicable for the purpose and favored the remission of the whole question to the committee. Professor Mach stated that as soon as he had thoroughly learned the Dewey system he had become a supporter of it and was of the opinion that some modification of the decimal system would be the best. Professor Dziatzko asserted that the Dewey system was not practicable even for large libraries. M. Otlet then spoke in favor of the Dewey system and explained the reason for its adoption by the Brussels Bibliographical Bureau.

Dr. Billings then spoke on the subject, delivering the longest address of the Conference. He said that the decimal system, known as the Dewey system, was a device for putting books in order on the shelves and a rapid method of finding them. It was simply a shorthand method of finding a book. The application of it to systematic catalogues was a different proposition. He asserted that the Dewey system is not accepted in any government library in the United States, or in any university library in the United States except Albany and Columbia, in both of which Mr. Dewey has been librarian. He said that less than 100 libraries were using the Dewey system and only about 32 the Cutter system. The Dewey system, however, was likely to grow because many young women who had been trained in Mr. Dewey's library school had taken charge of the catalogues of the smaller libraries in the United States, and the Library Bureau which had been founded by Mr. Dewey was providing a large series of useful appliances for librarians. He added: "I, for one, am disposed to award the greatest credit and admiration to Mr. Dewey, not only for the ingenuity which he has shown in this and other matters pertaining to library economy, but also for the ceaseless energy, zeal and persistence in getting the matter before the world and in having his ideas adopted as far as possible. I like to see a man believe himself, and in his own opinions, and do the best he can to put them into operation." He added, however, that the New York libraries, the Boston Public Library and the Boston Athenæum did not use the system and that it was not practicable for a systematic catalogue, even admitting its usefulness for the arrangement on the shelves.

Professor Schwalbe pointed out that even for library work the decimal system had many opponents, and he thought that some alphabetical system would be found the most practicable. Dr. Gill, representing Cape Colony, said that while the motion had brought out a good deal of condemnation of the Dewey system he had noticed that no other system had been put forward as perfect. Professor Armstrong said in reply that he did not think any other system was perfect, but that the object of the resolution was to put the matter in such shape as to leave entire freedom for action. Some considerable discussion followed without result, and Dr. Billings suggested that he would like to have a resolution of more practical value than the mere condemnation of one particular man's system. A long discussion followed on this point without result until Dr. Billings suggested that his object was to "get a declaration on the part of the conference that minute classification by means of symbols is not desirable in a catalogue. It is my opinion that no arrangement of the decimal system which you can propose, whether formed by Dewey or by others, is desirable." After some further discussion it was decided to adjourn until the next day, and on the morning of July 17th the resolution of the previous day was withdrawn and the following substituted: "The Conference, being unable to accept any of the systems of classification recently proposed, remits the study of classification to the Committee on Organization." This

resolution was seconded by Dr. Billings, who remarked that, inasmuch as one or two of his remarks of the day previous had been misunderstood by some members of the Congress, he wished distinctly to say that he did not condemn the Dewey decimal system for the classification and location of books, but he did not think it well adapted to the catalogue which it was proposed to publish. This resolution was now agreed to unanimously, the Belgian delegates desiring it to be placed on record that they abstained from voting.

Professor Deniker, representing France, now proposed: "That the catalogue according to the authors' names be in the English language, all titles to be also in their original language, unless otherwise desired by the Bureau of the country concerned." This resolution was seconded by General Ferrero, the Italian Ambassador. Professor Forel said that the question of language was one of very great importance, and he thought it should be remitted to the Committee of Organization, suggesting the following proposition: "With the questions of classification and form, the questions of the employment of four languages, German, English, French and Italian, shall be remitted to the Committee of Organization." Professor Mach, representing Austria, favored the employment of English as the only language, asserting that English is so widely spoken over the civilized world that it would be most proper to employ that language. "Every one," he said, "should respect his own nationality and his own language, but before that he should consider the universal interest of mankind." General Ferrero said that he supported the motion to use the English language because of precedent and of practicability. The official language of an international bureau should be the language of the country in which it is established; the Commission of Weights and Measures at Paris issued its publications in French, the Geodetic commission at Berlin in German. Professor Newcomb did not think it necessary to translate the titles of papers written in German, French or Italian into English. The discussion continued, many delegates taking part, until finally the following form was agreed upon: "That English be the language of the two catalogues authors' names and titles being given only in the original languages, except when this belongs to a category to be determined by the International Committee."

There was some little discussion as to whether the catalogue should begin January 1, 1900, or 1901, but the date 1900 was finally agreed to.

Professor Forel now made the following motion: "That when the organization for the catalogue is finally established it will be desirable to take in hand the publication of retrospective catalogues, carried out on the same plan, going back from century to century, as far back as the invention of printing." Dr. Billings objected to this resolution He held that it was not the business of the Conference to say what was desirable, but what was possible; that the Conference wanted to have the reputation of being a fairly sensible set of men who had not proposed to do anything which was beyond the reach of human effort properly organized. After further expressions of disapproval this resolution was withdrawn. The Conference then adjourned, with the customary votes of thanks.

Having adjourned, all the delegates presumably returned to their respective countries and made reports to their governments. The American delegates, Professor Simon Newcomb and Dr. John S. Billings, presented their report to the Secretary of State on October 15, 1896. On the following day the Secretary of State referred this report, in accordance with

the suggestion of the delegates, to the Secretary of the Smithsonian Institution, and asked for his views as to the propriety and feasibility of the work in question being undertaken by the Smithsonian Institution, and as to the probable cost, with a view to the departments taking the necessary action. A reply was forwarded to the Secretary of State and these documents transmitted by him to the Senate and House of Representatives. This was done on December 17, 1896.* Naturally enough no result has been reached. No money will be required until the year 1899–1900. But, in accordance with the terms of one of the articles, it is necessary that the countries which intend to adhere to the scheme should make their intention known before 1898. It is, therefore, most desirable that the first regular session of the 55th Congress should place itself on record as pledging the government of the United States to adhere to this plan, than which none has ever been proposed better calculated to promote the interest of science.

I cannot conclude without expressing my gratification, which I feel sure all your readers will share, in the honorable part taken by the United States in initiating this enterprise. It is but due to Dr. Billings and Professor Newcomb to recognize the great usefulness of their presence in aiding in the deliberations. Dr. Billings's long experience in bibliographical work gave his numerous recommendations great weight and they were uniformly adopted. The honor of American science demands that this country shall do its share toward bringing the proposed International Catalogue of Scientific Literature to a successful issue.

Cyrus Adler.

Smithsonian Institution,
Washington, D. C.

* The documents are appended.

APPENDIX.

The following is a selection from the resolutions agreed to :

4. That each delegate shall have a vote in deciding all questions brought before the Conference.

5. That English, French and German shall be the official languages of the Conference, but that it shall be open for any delegates to address the Conference in any other language, provided that he supplies for the proces verbal of the Conference a written translation of his remarks into one or other of the official languages.

6. General Ferrero moved that Sir John E. Gorst be the President of the Conference. The motion having been unanimously accepted,

7. Sir John Gorst nominated as Vice-Presidents: General Ferrero, Professor Darboux, Professor Mach, Professor Möbius, Professor Newcomb. It was further resolved :

8. That Professor Armstrong be the Secretary for the English Language ; that Professor Forel be the Secretary for the French language ; that Professor Dyck be the Secretary for the German language.

9. That the Secretaries, with the help of shorthand reporters, be responsible for the proces verbal of the proceedings of the Conference in their respective languages.

12. That it is desirable to compile and publish by means of some international organization a complete Catalogue of Scientific Literature, arranged according to both subject-matter and to authors' names.

13. That in preparing such a catalogue regard shall, in the first instance, be had to the requirements of scientific investigators, to the end that these may, by means of the catalogue, find out most easily what has been published concerning any particular subject of inquiry.

14. That the administration of such a catalogue be entrusted to a representative body, hereinafter called the International Council, the members of which shall be chosen as hereinafter provided.

15. That the final editing and the publication of the catalogue be entrusted to an organization, hereinafter called the Central International Bureau, under the direction of the International Council.

16. That any country which shall declare its willingness to undertake the task shall be entrusted with the duty of collecting, provisionally classifying, and transmitting to the Central Bureau, in accordance with rules laid down by the International Council, all the entries belonging to the scientific literature of that country.

17. That in indexing according to subject-matter regard shall be had, not only to the title (of a paper or book), but also to the nature of the contents.

18. That the catalogue shall comprise all published original contributions to the branches of science hereinafter mentioned, whether appearing in periodicals or in the publications of societies or as independent pamphlets, memoirs, or books.

20. That in each country the system of collecting and preparing material for the catalogue shall be subject to the approval of the International Council.

21. That in judging whether a publication is to be considered as a contribution to science suitable for entry in the catalogue, regard shall be had to its contents, irrespective of the channel through which it is published.

22. That the Central Bureau shall issue the catalogue in the form of 'slips' or 'cards,' the details of the cards to be hereafter determined, and the issue to take place as promptly as possible. Cards corresponding to any one or more branches of science, or to sections of such sciences, shall be supplied separately and under the direction of the Central Bureau.

23. That the Central Bureau shall also issue the catalogue in book form from time to time, the entries being classified according to the rules to be hereafter determined.

That the issue in the book form shall be in parts corresponding to the several branches of science, the several parts being supplied separately, at the discretion and under the direction of the Central Bureau.

24. That the Central Bureau be located in London.

The resolution was seconded by M. Darboux, supported by Messrs. Möbius, Heller, Weiss, Simon, Newcomb, Otlet, Duka, Bourcart, Dahlgreen and Korteweg, and accepted by acclamation.

25. That a contribution to science for the purpose of the catalogue be considered to mean a contribution to the mathematical, physical, or natural sciences, such as, for example, mathematics, astronomy, physics, chemistry, mineralogy, geology, botany, mathematical and physical geography, zoology, anatomy, physiology, general and experimental pathology, experimental psychology and anthropology, to the exclusion of what are sometimes called the applied sciences—the limits of the several sciences to be determined hereafter.

26. That the Royal Society be requested to form a committee to study all questions relating to the catalogue referred to it by the Conference, or remaining undecided at the close of the present sittings of the Conference, and report thereon to the governments concerned.

27. Since it is probable that, if organizations be established in accordance with Resolution 16, the Guarantee Fund required for the Central Bureau can be supplied by voluntary subscriptions in various countries, this Conference does not think it necessary at present to appeal to any of the governments represented at the Conference for financial aid for the Central Bureau.

28. The Conference being unable to accept any of the systems of classification recently proposed, remits the study of classifications to the Committee of Organization.

29. That English be the language of the two catalogues, authors' names and titles being given only in the original languages except when these belong to a category to be determined by the International Council.

30. That it be left to the Committee (of the Royal Society) to suggest such details as will render the catalogue of the greatest possible use to those unfamiliar with English.

31. That it is desirable that the Royal Society should be informed, at a date not later than January 1, 1898, what steps (if any) are being taken, or are likely to be taken, in the countries whose governments are represented at the Conference, towards establishing organizations for the purpose of securing the end had in view in Resolution 16.

32. That the delegates in reporting to their respective governments the proceedings of the Conference should call immediate attention to Resolutions 16 and 31.

33. That January 1, 1900, be fixed as the date of the beginning of the catalogue.

34. That the Royal Society be requested to undertake the editing, publication and distribution of a verbatim report of the Proceedings of the Conference.

35. That the proces verbal of the Conference be signed by the President and Secretaries.

Letter from the Secretary of State, transmitting with the draft of a proposed joint resolution and inclosures from the Secretary of the Smithsonian Institution, recommendations for an appropriation to enable the United States to participate in the work of making an International Catalogue of Scientific Works.

DEPARTMENT OF STATE,
Washington, December 17, 1896.

SIR: I have the honor to transmit, herewith, the report of Professor Simon Newcomb and Dr. John S. Billings, delegates from this country to the International Conference on a Catalogue of Scientific Literature, held in London in July last by request of the Royal Society, and having for its object an international agreement as to the steps necessary to the preparation, editing and continuous publication of the current scientific literature of all countries.

It will be seen that by the thirty-second resolution formulated by the Conference the delegates were especially requested to bring the following two resolu-

tions to the attention to their respective governments:

16. That any country which shall declare its willingness to undertake the task shall be entrusted with the duty of collecting, provisionally classifying, and transmitting to the Central Bureau, in accordance with rules laid down by the International Council, all the entries belonging to the scientific literature of that country.

31. That it is desirable that the Royal Society should be informed, at a date not later than January 1, 1898, what steps, if any, are being taken, or are likely to be taken, in the countries whose governments are represented at the Conference, toward the establishing of organizations for the purpose of securing the end had in view in Resolution 16.

In the opinion of Professor Newcomb and Dr. Billings, it is desirable that the government of the United States should take its part in the proposed work by providing for the continuous cataloguing of scientific papers published in the United States, and they suggest the propriety and feasibility of the work being undertaken by the Smithsonian Institution.

Professor S. P. Langley, Secretary of that Institution, to whom I have submitted the report of the delegates, concurs in their view as to the great importance of a successful execution of the conclusions of the Conference, and as to the propriety of this government taking its share of the proposed work by providing for the cataloguing of scientific publications of the United States. He recognizes the propriety also of the suggestion that this government should employ the Smithsonian Institution as an agent in the matter, but points out that the work if assigned to the Smithsonian would require a person of special qualifications to immediately assist the Secretary, together with a number of trained clerical assistants, and that the salaries of these persons, and the expenses incident to the work, would require an appropriation of not less than $10,000 per annum. I enclose a copy of Professor Langley's letter on the subject.

The most efficient means for the purpose would seem to be a joint resolution of both Houses of Congress, and I have the honor to suggest the inclosed draft as embodying Professor Langley's views.

I have the honor to be, sir, your obedient servant,

RICHARD OLNEY.

HON. THOMAS B. REED,

Speaker of the House of Representatives.

WASHINGTON, D. C., *October 15, 1896.*

SIR: The undersigned having been appointed by the Honorable the Secretary of State delegates to the International Conference on a Catalogue of Scientific Literature, held in London in July last by request of the Royal Society, and having performed the duty thus devolving upon them, have the honor to submit the following report on the subject:

The object of the Conference was to reach an international agreement as to the steps necessary to the preparation, editing and continuous publication of a catalogue of the current scientific literature of all countries. The need of such a catalogue has been felt from the time that the volume of published scientific researches began to assume its present colossal proportions. About 1860 the Royal Society undertook to supply this need by the preparation of a general catalogue of scientific papers. The first volume of this work appeared in 1867. In the preface it is stated that the undertaking originated in a communication from Dr. Joseph Henry, Secretary of the Smithsonian Institution, to the meeting of the British Association at Glasgow in 1855, suggesting the formation of a catalogue of philosophical memoirs.

This work has been completed by the Royal Society up to the year 1883. In the meantime, owing to the constant increase of the volume of published researches, the task of continuing the catalogue has become so heavy that the Royal Society should no longer be expected to bear the entire burden of its continuance. Moreover, in its present form, the catalogue is arranged solely according to authors' names. In order that the work of the future should be entirely satisfactory it is necessary that the catalogue should also be arranged according to subjects.

Under these circumstances, the Royal Society last year moved the British government to make application to the governments of those countries most interested to send delegates to an international conference on the subject, to be held in London in July, 1896. At this meeting nearly all the leading countries of the world were represented. From the beginning the views were found to be substantially harmonious so far as general conclusions were concerned, and the discussion turned rather upon the form than upon the substance of the proposition submitted. The conclusions as finally formulated are embodied in the enclosed copy of the acta.

It will be seen by the thirty-second resolution the delegates were especially requested to bring the following two resolutions to the attention of their respective governments:

16. That any country which shall declare its willingness to undertake the task shall be entrusted with the duty of collecting, provisionally classifying, and transmitting to the Central Bureau, in accordance with rules laid down by the International Council, all the entries belonging to the scientific literature of that country.

31. That it is desirable that the Royal Society should be informed at a date not later than January 1, 1896 (1897),* what steps, if any, are being taken,

* The report of the Conference gives the date January 1, 1898.

or are likely to be taken, in the countries whose governments are represented at the Conference, toward establishing organizations for the purpose of securing the end had in view in Resolution 16.

Under these circumstances it seems especially desirable that the government of the United States should take its part in the proposed work by providing for the continuous cataloguing of scientific papers published in the United States. It can for this purpose call to its aid a national institution well prepared to direct and supervise the undertaking. The Smithsonian Institution, founded by private munificence for the increase and diffusion of knowledge among men and placed in trust under the government of the United States, was the original proposer of the undertaking now under consideration, and has been made the agent of the government in the direction of important scientific enterprises. We would, therefore, respectfully suggest that the Department of State communicate with the Secretary of the Smithsonian Institution upon this subject, more especially as to the propriety and feasibility of the work being undertaken by that Institution and as to the probable expense, and that when these facts are ascertained the matter will be laid before Congress with such recommendation as the Department, in its wisdom, may deem appropriate.

Very respectfully, your obedient servants,

SIMON NEWCOMB,
JOHN S. BILLINGS.

The SECRETARY OF STATE,
Department of State, Washington, D. C.

SMITHSONIAN INSTITUTION,
Washington, October 27, 1896.

SIR: I have the honor to acknowledge the receipt of your communications of the 16th and 21st instant, inclosing copies of a report of the delegates of this government to the International Conference on a Catalogue of Scientific Literature, summoned in London by the British government at the request of the Royal Society in July last, and inviting an expression of my opinion as to the propriety and feasibility of the United States taking part, through the Smithsonian Institution, in the proposed work by providing for the continuous cataloguing of scientific literature published in the United States, as suggested by the delegates, and further requesting an estimate of the probable expense attendant thereto.

I fully concur in the view of the delegates as to the great importance of a successful execution of the conclusions of the Conference, and as to the propriety of this government taking its share of the proposed work by providing for the cataloguing of the scientific publications of the United States. This opinion is strengthened by the fact that the recommendations made are due to results emanating from the International Conference, at which the United States was officially represented, and by the further considerations that the benefits to be derived from this undertaking are not only great and far-reaching for the scientific progress of America, but also of universal value, and that all the great and many of the smaller nations will take part in the work.

I recognize also the propriety of the suggestion that the government should employ the Smithsonian Institution as an agent in this matter, particularly since the Institution, as the delegates have pointed out, first suggested this subject in 1855, and since it has been from its earliest organizat on interested in scientific bibliogrophy.

I should, however, be reluctant to commit the Institution to the appearance of soliciting Congress in this matter in any case, or to the undertaking of the enterprise, however worthy, unless provision could be made for the necessary expenses of the work. After considering the subject, it seems to me that the work, if assigned to the Smithsonian Institution, would require a person of special qualifications to immediately assist the Secretary, together with a number of trained clerical assistants, and that the salaries for these persons and the expenses incident to the work would require an appropriation of not less than $10,000 per annum.

Expenditures on this appropriation would probably not need to be available before the fiscal year commencing July 1, 1899, though it would seem to be advisable that if the government is to cooperate in the proposed work there should be some earlier assurance of this.

Should the views here given meet with your approval, I venture to express the hope that the Department of State will bring this matter to the attention of the President for transmission to Congress, as was done on a previous occasion when the Institution was requested to assume the care of the international exchange of publications in behalf of the government.

I have, etc.,

S. P. LANGLEY,
Secretary.

HON. RICHARD OLNEY,
Secretary of State.

Resolved by the Senate and the House of Representatives of the United States of America in Congress assembled, That for the purpose of carrying out on the part of the United States the recommendation of the International Conference on a Catalogue of Scientific Literature, held in London in July, eighteen hundred and ninety-six, the sum of ten thousand dollars, or so much thereof as may be necessary, be, and the same is hereby, appropriated, out of any money in the Treasury not otherwise appropriated, for the

expense of clerk hire and the other expenses incident to the work of cataloguing the scientific publications of the United States, the same to be expended under the direction of the Secretary of the Smithsonian Institution.

BRITISH ASSOCIATION, TORONTO MEETING.

THE second Canadian meeting of the British Association will commence in Toronto August 18th, and will continue for eight days. Present indications are that a very large number of British visitors will be in attendance, amongst whom will be found some of the most representative men of British science. About twenty Continental savants, also of representative character, will attend.

Arrangements have been made by the Council of the British Association whereby the members of the American Association are entitled to become annual members of the British Association on the payment of a fee of $5.00. Those who are not members of the American Association can become annual members on the payment of $10.00 or associate members on payment of $5.00. Arrangements are now made whereby the application for membership can be made to one of the local Treasurers of the Association, Mr. James Bain, British Association office. For the convenience of Americans who propose to attend the Toronto meeting, a list of lodgings and apartments as well as a list of hotels has been published and copies of these may be had upon application to the local Secretaries at Toronto. American members of the British Association are entitled to travel in Canada east of Port Arthur at half the usual charge for first-class tickets, this privilege beginning on July 1st and expiring on September 30th. In order to enable the members to receive this privilege they must be provided with what is called a railway certificate, which can be had on personal application to the local officers at Toronto or to the railway officers at Montreal. The presentation of this certificate at any office will at once enable the holder of it to receive reduced railway rates. Such members also will be entitled to reduced rates for a trip over the Canadian Pacific Railway from Toronto to points in western Canada. The rate from Toronto to the Pacific coast and return varies from $61.80 to 70.30, according to the route selected. This does not include the Pullman fare, for which an extra charge will be made.

The various excursions which are arranged for will take place either during the meeting from Saturday, August 21st, to Monday, August 23d, or immediately after it, on Thursday, 26th, 27th and 28th, and will be made at reduced rates. The excursion to Muskoka, which will be for about four hundred, embracing a run of a hundred and ten miles by rail, with a sail over the Muskoka lakes, will cost $1.65. The excursion from Toronto to Niagara will cost $1.25.

The office of the British Association, will be in the University of Toronto building. All the meetings of the Association excepting those for the President's address and the two evening lectures, will be held in the lecture rooms and laboratories of the University of Toronto. The President's address is to be delivered in Massey Hall, where also will be given the two evening lectures by Professor John Milne and Professor Roberts-Austen. The free lectures on Borneo to artisans will be given by Dr. H. O. Forbes, in the Horticultural Pavilion.

According to the scheme of the local provisional program, the time of the members will be pretty fully occupied. The first General Committee meeting of the Association will take place on the afternoon of Wednesday, August 18th. The President's address will be delivered on the evening of the same day. The Sections will meet on Thursday, August 19th, and the addresses of the Presidents will be then given. In the afternoon of the same day

there will be a large garden party given at the Royal Canadian Yacht Club, Toronto Island. His Excellency, the Governor-General, and the Countess of Aberdeen will in the evening give a reception to the members in the Parliament buildings of the Province of Ontario. On Friday there will be meetings of the Sections until about three o'clock, when there will be a Convocation of the University of Toronto to confer the Honorary Degree of Doctor of Laws upon Lord Kelvin, Lord Lister, Sir John Evans and the President of the American Association, Professor Wolcott Gibbs. After Convocation is over there will be several garden parties for the members. In the evening will be the lecture of Professor Roberts-Austen, F. R. S., on 'Canada's Metals.' This will be illustrated by demonstrations of electric furnaces in the reduction and separation of the various metals. On Saturday morning the Sections will meet and adjourn early, in order that the members may take the various excursions which are arranged for from Saturday to Monday. The members will be offered a choice in these, there being four routes, one to Muskoka, the lake region of Canada, a second to Niagara Falls, a third to Hamilton and Dundas, thence to Niagara Falls, a fourth to Georgian Bay. The members of the Geological Section are to visit and examine the Niagara Gorge, under the guidance of Messrs. G. K. Gilbert, J. W. Spencer and F. B. Taylor, all of whom have given special attention to the geology of the Niagara region. Arrangements are being made whereby members of this party will have an opportunity of going up by the Gorge Railway and returning by the Niagara Falls and Victoria Park Railway or *vice versa.* These two trips will enable them to cover all the special points of interest in connection with the much debated geology of Niagara Falls.

Members of the Section for Mechanical Science will also visit Niagara to examine the Hydraulic Companies' works and the plant for the manufacture of carborundum. The various Hydraulic Power Companies have extended a special invitation to the members of the Association, and it is expected that a large number will avail themselves of the privilege accorded. It is probable that amongst the visitors on this occasion will be a large number of the most eminent electricians and engineers.

The excursionists to Muskoka will stay at the various hotels and lodging houses in the Muskoka region over Sunday. Another party will have an opportunity of visiting the many thousand islands in Georgian Bay. This group will go partly by rail to Penetang, thence by boat through Georgian Bay to Parry Sound, returning on Monday morning. On Monday the majority of the Sections will again meet. On Monday afternoon the Geological Section will examine the glacial region of Scarboro' Heights and the Don Valley, which are of special interest to students of the glacial age, the deposits there being very extensive and of great thickness. A number of garden parties are also arranged for the members during this afternoon.

In the evening Professor John Milne, F.R.S., recently of the University of Tokyo, will deliver an illustrated lecture with demonstrations on 'Earthquakes and Volcanoes.' On Tuesday morning the Sections will again meet. In the afternoon there will be a Convocation of Trinity University to confer the Honorary Degree of D.C.L. on Lord Lister, Sir John Evans and Professor Forsyth, this ceremony being followed by several garden parties. In the evening there will be a Conversazione with music and refreshments in the main building of the University of Toronto for all the members of the Association. On Wednesday the Sections will meet for their con-

cluding meeting, and in the afternoon the second and last general meeting of the Association will take place. In the evening a banquet will be given in honor of Lord Kelvin, Lord Lister and Sir John Evans, at which there will probably be in all about four hundred guests. It is proposed to reserve a number of tickets, about seventy-five, for those who may not have an opportunity of claiming one at an earlier date.

The full number of Sections will meet at Toronto. Within the last few years the number has increased from eight to ten, the increase being due to the removal of Physiology and Botany from Section D (Biology), which is now called Zoology. Section I (Physiology) only meets where there is a physiological laboratory, and consequently it will be in session at Toronto. The Presidents of the various Sections have been specially chosen for the Toronto meeting: Professor Forsyth, D.Sc., F.R.S., of the University of Cambridge, for Mathematics (Section A); Professor William Ramsay, Ph.D., F.R.S., for Section B (Chemistry); Dr. G. M. Dawson, C.M.G., F.R.S., Director of the Dominion Geological Survey for Section C (Geology); Professor L. C. Miall, F.R.S., F.L.S., for Section D (Zoology); Dr. J. Scott Keltie, Sec. R.G.S, for Section E (Geography); Professor Gonner, M.A., for Section F (Economic Science and Statistics); G. F. Deacon, M.Inst.C.E., for Section G (Mechanical Science); Sir William Turner, F.R.S., for Section H (Anthropology); Professor Michael Foster, Sec. R.S., for Section I (Physiology); Professor H. Marshall Ward, F.R.S., for Section K (Botany).

Amongst the British members who have promised to attend are the following:

Professor W. E. Ayrton, F.R.S., City and Guilds of London Institute.

Professor Henry E. Armstrong, Ph.D., LL.D., F.R.S, City and Guilds of London Institute.

E. W. Brabrook, F.S.A., London.

Colonel F. Bailey, Sec.R.Scot.G.S., F.R.G.S., Edinburgh.

Professor F. O. Bower, D.Sc., F.R.S., The University, Glasgow.

Professor W. F. Barrett, F.R.S.E., M.R.I.A., Royal College of Science, Dublin.

J. T. Bottomley, D.Sc., F.R.S., The University, Glasgow.

Professor T. Hudson Beare, M.Inst.C.E., F.R.S.E., University College, London.

Professor Francis Gibson Bailey, Heriot Watt College, Edinburgh.

Professor C. V. Boys, F.R.S., Royal College of Science, London.

The Right Hon. James Bryce, M. P., London, Eng.

Professor Rubert Boyce, M.D., University College, Liverpool.

G. F. Deacon, M.Inst.C.E., London, Eng.

Harold B. Dixon, M.A., F.R.S., F.C.S., Owens College, Manchester.

Sir John Evans, K.C.B., D.C.L., LL.D., D.Sc., Treas. R.S., F.S.A., F.L.S., F.G.S., etc., Nash Mills, Hemel Hempstead, Eng.

Professor J. A. Ewing, M.A., B.Sc., F.R.S., F.R.S E., M.Inst.C. E., University of Cambridge.

Professor A. R. Forsyth, M.A., D.Sc., F.R.S., University of Cambridge.

Professor C. Le Neve Foster, B.A., D Sc., F.R.S., F.G.S., Royal College of Science, London.

Professor G. Carey Foster, F.R.S., F.C.S., University College, London.

Professor Michael Foster, M.A., M.D., LL.D, D.C.L., Sec.R.S., F.L.S., F.C.S., University of Cambridge.

Hon. Sir. C. W. Fremantle, K.C.B., London.

Henry O. Forbes, LL.D., F.Z.S., The Museums, Liverpool.

Professor George F. Fitzgerald, D.Sc., F.R.S., Trinity College, Dublin.

Professor J. Reynolds Green, B.Sc., F.R.S., F.L.S., Professor of Botany to the Pharmaceutical Society of Great Britain.

Walter H. Gaskell, M.D., LL.D., F.R.S., Cambridge.

Professor A. G. Greenhill, M.A., F.R.S., Artillery College, Woolwich, Eng.

Professor E. C. K. Gonner, M.A., University College, Liverpool.

E. Sidney Hartland, F.S.A.,

Henry Higgs, LL.B., F.S.S.

Professor W. H. Heaton, University College, Nottingham.

Professor W. A. Herdman, F.R.S., D.Sc., F.R.S.E., University College, Liverpool.

Alfred C. Haddon, M.A., F.G.S., Cambridge.

Professor W. O. Halliburton, M.D., F.R.S., King's College, London.

A. Vernon Harcourt, D.C.D., LL.D., F.R.S., Cowley Grange, Oxford.

L. F. Vernon Harcourt, M.A., M.Ins.C.E., London, Eng.

J. Scott Keltie, LL.D., Sec. R.G.S., London.

The Right Hon. the Lord Kelvin, M.A., LL.D., D.C.L., F.R.S., F.R.S.E., University of Glasgow.

Prince Kropotkin, South Acton, London.

G. W. Lamplugh, F.G.S., Geological Survey Office, London Eng.

The Right Hon. the Lord Lister, D.C.L., Pres.R.S., etc., London, Eng.

Professor Oliver J. Lodge, D.Sc., LL.D., F.G.S., University College, Liverpool.
Hugh Robert Mill, D.Sc., F.R.S.E., London, Eng.
Professor Henry A. Miers, F.R.S., F.G.S., Magdalen College, Oxford.
Professor John Milne, F.R.S., F.G.S., Isle of Wight.
Robert Munro, M.A., M.D., Edinburgh.
L. C. Miall, F.R.S., F.L.S., F.G.S., Yorkshire College, Leeds.
Professor Raphael Meldola, F.R.S., F.R.A.S., Finsbury Technical College, London.
Professor Meslans, University of Nancy, France.
Dr. Donald Macalister, M.A., M.D., Cambridge.
John L. Myres, M.A., F.S.A., Oxford.
Professor Edward B. Poulton, F.R.S., F.L.S., University of Oxford.
W. H. Preece, C.B., F.R.S., M.Inst.C.E., Wimbledon Common, Surrey.
Professor W. C. Roberts-Austen, C.B., Royal Mint London.
E. G. Ravenstein, F.R.G.S., F.S.S., London.
Wm. Ramsay, Ph.D., F.R.S., F.C.S., University College, London.
Arthur W. Rucker, M.A., D.Sc., F.R.S., Professor of Physics in the Royal College of Science, London.
Robert Saundby, M.D., F.R.S.P., Birmingham.
A. C. Seward, M.A., F.G.S., Cambridge, Eng.
Professor C. S. Sherrington, M.D., F.R.S., University College, Liverpool.
Sir William Turner, M.B., LL.D., D.C.L., F.R.S., University of Edinburgh.
Professor W. H. Thompson, M.D., Queen's College, Belfast.
Professor William Cawthorne Unwin, F.R.S., M.Inst.C.E., City and Guilds of London Inst.
Professor F. E. Weiss, B.Sc., F.L.S., Owens College, Manchester.
Professor H. Marshall Ward, D.Sc., F.R.S., F.L.S., Cambridge, University.
Professor W. G. Adams, M.A., F.R.S., F.G.S., King's College, London.
Professor Henrici, Ph.D., F.R.S., City and Guilds of London Institute.
Professor Major P. A. McMahon, R.A., F.R.S., Artillery College, Woolwich.
H. W. Seton-Karr, Esq., Wimbledon, Surrey.
Professor John Perry, D.Sc., F.R.S., London, Eng.
Walter Garstang, M.A., F.Z.S., Marine Biologieal Laboratory, Plymouth.
The Rt. Hon. the Earl of Berkeley, Abingdon.
Professor E. M. Crookshank, King's College, London.
G. Griffith, M.A. (Asst.Gen.Sec.), Harrow.
Professor H. McLeod, F.R.S., F.C.S., Royal Indian Civil Engineering College.
Professor C. Lloyd Morgan, F.G.S., Principal, University College, Bristol.
Professor S. P. Thompson, B.A., F.R.S., D.Sc., F.R.A.S., City and Guilds of London Technical College.
Dr. A. W. Waller, F.R.S., London, Eng.
W. T. Blanford, LL.D., F.R.S., F.G.S., London, Eng.
F. C. Selous, Esq., Wargrove, Bucks.
Sir Malcolm Fraser, General Agent for Western Australia.
Dr. D. Noel Paton, Edinburgh.
John A. Campbell, M.D., F.R.S., Carlisle, Eng.
Sir George S. Robertson, K.C.S.I., London, Eng.
Professor Anderson Stuart, University of Sydney, New South Wales.
Major-General Webber, C.B., R.E., M.Inst. C.E.

The following men of science from the Continent are to be present:

Professor Dr. Anton Dohrn, Zoological Station, Naples.
Professor Yves Delage, University of Paris.
Gustave Gilson, University of Louvain, Belgium.
A. Gobert, Brussels.
Professor Dr. Albert Ladenburg, Breslau.
Professor Meslans, University of Nancy, France.
Professor P. Magnus, University of Berlin.
Dr. Ph. Pauli, Frankfurt-am-Main.
Dr. van Rijckevorsel, Netherlands.
Professor C. Runge, Hannover.
Professor Charles Richet, Paris.
Professor Bohuslav Brauner, University of Prag.
Professor Braun, University of Strassburg.
Professor Fittica, University of Marburg, Germany.
Professor K. Hürthle, University of Breslau.
Professor Penck, University of Vienna.

A. B. MACALLUM.

DE VOLSON WOOD.

PROFESSOR DE VOLSON WOOD, whose death was recently noticed in this JOURNAL, was a man of unusual attainments and was for nearly half a century identified with the promotion of that systematic technological education which has come to play so important a rôle in the civilization of the present day. He was born in 1832, and passed the years of his youth on the farm of his father near Smyrna, N. Y. He early displayed the capacities of a successful student and teacher of mathematics. The neighbors used to say that "the stones on Mr. Wood's farm are covered with figures which his son De Volson had used in the solution of problems;" and he began teaching school at the age of 17. After some preliminary studies in a private academy and at Cazenovia Seminary, he went to Albany State Normal School in 1852 and was graduated from that Institution at the end of the following year. During 1853–4 he was principal of the public school of Nopanoch, N. Y.; and during 1854–5 he served the Albany Normal School as assistant professor of mathematics. He then

went to the Rensselaer Polytechnic Institute of Troy, N. Y., where, after two years' work as student and instructor, he was graduated with the degree of civil engineer. Immediately thereafter he became connected with Michigan University, in which he served as assistant professor of civil engineering from 1857 to 1859, as professor of physics and engineering from 1859 to 1860 and as professor of civil engineering from 1860 to 1872. At the end of the latter academic year he resigned his professorship in Michigan University to accept the professorship of mathematics and mechanics in Stevens Institute of Technology, which had been founded the same year. He remained with this institution until his death, holding the professorship of mathematics and mechanics until 1885, and from that year on the professorship of mechanical engineering.

It is an interesting circumstance, which in some measure undoubtedly determined Professor Wood's career, that he went to Michigan University shortly after President Henry Philip Tappan began his remarkable educational work in that institution. Tappan, considering the time in question, was a man of very broad and liberal views concerning educational affairs, and was one of the first to introduce in this country the German ideas of the functions and administration of a university. He was also one of the first of our educators to recognize the value of technological studies, and under his guidance there was established in Michigan University as early as 1855 a four years' course in engineering, to the conduct of which Professor Wood was called two years later. Two other brilliant men of the same institution into whose association Professor Wood was thrown at this time were the distinguished astronomers Francis Brünnow and James C. Watson. A more stimulating intellectual environment than that furnished by these three men could not have been found in this country at that time.

From the time he went to Michigan University, in 1857, to the end of the present academic year Professor Wood was actively engaged in the work of instruction, rarely missing a day from his class-room in forty-one years. During the earlier part, especially, of this long interval, before the differentiation of studies now common had been attained, he gave instruction in a variety of subjects, embracing in fact nearly all those of the mathematico-physical sciences in the engineering curriculum. He was thus brought into intimate contact, and in many cases into prolonged association, with a large body of students who have borne abundant testimony to the exceptional value of his instruction and influence by the range and efficiency of the work they have accomplished. The peculiar merit of his teaching lay in his capacity to make men think laboriously and enthusiastically with their own heads. He was usually able to get students to devote willingly to his subjects three to five times as much labor as they would give to the subjects of other instructors. Being also himself a man of untiring industry, full of suggestions and enquiries, and animated always by a robust and transparent love of the truth, only the dullest students could fail to make creditable progress under his guidance. This genius for industry and this capacity for self-help are the elements of character he succeeded in planting firmly in the long list of engineers who had the good fortune to come under his instruction.

Professor Wood was a frequent contributor to scientific periodicals, particularly those devoted to mathematics and engineering. He was also the author of several text-books widely used in schools of engineering. In this work, as in teaching, his activity was indefatigable to the last, a revised and enlarged edition of his important

work on water motors having been brought out shortly before his death.

In appearance Professor Wood was a striking figure. His large, erect frame and his energetic manner at once commanded attention and respect. Socially he was a most genial and kindly man, full of patience and encouragement, especially for young men. He was of a somewhat retiring and domestic disposition, however, and mingled less with men of the world than might have been expected. Though honored by election to office in the scientific societies to which he belonged, he never sought personal advancement. He was content with his chosen work in the class-room, and the remarkable success he attained in that work amply justifies the singular fidelity with which he devoted his life to it.

CURRENT NOTES ON PHYSIOGRAPHY.

THE LABRADOR PENINSULA.

Much interesting information about Labrador is to be found in an article by Low in the Annual Report of the Geological Survey of Canada for 1895 (Ottawa, 1897). The fiords of the Atlantic coast are described as valleys of denudation of very ancient origin, eroded when the elevation of the peninsula was greater than now. "Their remote antiquity is established by the deposition in their lower levels of undisturbed sandstones of Cambrian age." A similar explanation is given to the greater river valleys. The 'banks' for some fifteen miles off the coast are shallower than many of the fiords; they are explained as a terminal moraine, somewhat flattened out by floating ice and currents. At least a fourth of the plateau area is occupied by lakes of small depth confined in shallow valleys by barriers of drift. Some of the larger and deeper lakes occupy ancient basins, floored with Cambrian strata. There is a lakeless plain of marine sands and clays carved by deep stream channels, extending inland for a hundred miles eastward from James bay. Much is told about Hamilton river, with its Grand Falls, and Bowdoin* Cañon below them, from which a clear picture of the plateau region may be gained. Erosion by ice is given a small measure; its chief result being to rub down hills and fill neighboring depressions, thus decreasing local relief. "There is no evidence to show that the glacier ever hollowed or scooped out deep depressions, as has been often stated to have occurred elsewhere." The till is frequently arranged in long low ridges, like drumlins, with nearly driftless tracts between them. Eskers are greatly developed, one having a length of nearly a hundred miles. They are ascribed to streams flowing on or below the ice when the glacial sheet had become practically stagnant.

It is difficult to reconcile the statements noted above as to the age of the fiords, the greater valleys and the deeper lakes, with the rates of denudation in resistant rocks elsewhere, unless it be supposed that for most of geological time the Labrador plateau has been covered by an inert ice sheet, protective of very ancient forms rather than productive of new forms; or unless it be supposed that the depressions were long ago made and filled and rather lately re-excavated. In any case, it is hardly possible that "the process of formation of these valleys has continued slowly from [Cambrian time] to the present day by the agency of falling water and of frost." Does the earth's surface exhibit any rocks resistant enough to retain significant slopes after so long an attack of the destructive subaërial forces?

THE CHICAGO AREA.

Leverett describes the Pleistocene features and deposits of the Chicago area

*Bowdoin is unfortunately misspelled *Bodwoin* in the report and on the accompanying map of Labrador.

(Bull. II., Geol. and Nat. Hist. Survey, Chicago Acad. Sciences, May, 1897), including the Valparaiso moraine, the channel cut by the former outlet of Lake Michigan through the moraine and down the Illinois river valley, and the beaches of the former lake. The moraine is concentric with the present lake shore; it is a hilly belt, about ten miles wide and a hundred or more feet higher at the 'crest' than at the borders; its mounds frequently enclose hollows and lakelets. The channel cut by the former lake outlet follows a drift-clogged valley of preglacial origin below Hennepin (where the Illinois river turns from west to south), but is of glacial or post-glacial origin above that point. It is from one to five miles wide, and from 20 to 70 feet deep; its marginal bluffs are steep, like a river bank, throughout the entire length of 300 miles, as if the lake outflow had great volume, filling the channel from bluff to bluff. Three beaches are described, marking the lake shore at the time of the westward outflow. It should here be remembered that the slight difference between the level of the old outlet and of the present lake is not due simply to a slight withdrawal of the waters, but is due to a strong rise of the waters after a strong fall, as has been well shown by several students of the glacial history of the Great Lakes; the fall resulting from the adoption of eastern outlets, and the rise resulting from an elevation of the land in the northeast. So close a return to the Illinois outlet is portentous of the future.

STUDIES IN INDIANA GEOGRAPHY.

SEVERAL papers on the geography of Indiana by various authors have been published in the *Inland Educator* during the past year, and some of them have been referred to in these notes. The whole series is now edited by C. R. Dryer, professor of geography in the Indiana State Normal School, and published in book form (Inland Publishing Co., Terre Haute, Ind., 1897). 'First series' appears on the title page, as if more essays are to follow; and it is to be hoped that such is the case, for much educational good must result from the careful use of such material by teachers. The book is notable in being the first of a kind that should have great extension over the country, as an encouragement and assistance in the study of home geography. There is to-day no similar series of essays even for States as prosperous and as important as Ohio and Pennsylvania. Indeed, it is a difficult matter for the inquiring teacher to find available geographical literature for her work. Professors of geography in other normal schools might well follow the example set by Dryer.

CURRENT NOTES ON ANTHROPOLOGY.

ANTIQUITY OF MAN IN SWITZERLAND.

THE thirty-fifth volume of the Memoirs of the *Société Helvétique des Sciences Naturelles* is taken up with a thorough analysis of cave exploration near the Rhine, by Dr. Jacob Nuesch and his collaborators. The conclusions he reaches are the more noteworthy because they were obtained after the most exhaustive investigations and comparisons of the fauna, flora and human remains exhumed from the cave-floors. They may be briefly summed up as follows:

The oldest faunas found were sub-arctic and post-glacial. Man was contemporaneous with these, and at that time his industries were distinctly palæolithic. This period lasted about 8,000 years. A long period then elapsed, 8,000 to 12,000 years, during which the fauna changed to modern types, but man seems to have been absent. The neolithic and lake-dwelling period then

began and continued about 4,000 years, closing with the introduction of bronze about 4,000 years ago.

This makes about 28,000 years since man first appeared on Swiss soil; but it must be borne in mind that he may have flourished in milder parts of the continent for indefinite ages before that. The vast Alpine glaciers rendered the climate of Switzerland uninviting long after the continental glacial period had ceased.

MOKI CEREMONIALS.

An instructive article for the student of primitive religions is that by Dr. J. Walter Fewkes on 'The Group of Tusayan Ceremonials called *Katcinas*.' (15th Rep. Bureau of Ethnology.) It is a faithful narration of the strange religious performances, amply illustrated, and the native terms preserved wherever possible.

The word *Katcina* is a vague term for spiritual beings of an inferior class to the highest deities of the tribe, but who are credited with much power over the welfare of the community. They may include the ancestral souls, but are not exclusively these. The ceremonies in their honor are frequent, and distributed throughout the year in a ritual calendar devised by the priestly class. Both men and women participate in them, and they have the character of a sacred drama, as have most primitive rituals. Masks, costumes and traditional songs and chants are prominent features.

Dr. Fewkes finds noticeable resemblances between these ceremonials and those of other Pueblos, but also marked differences. He is impressed with their analogies to those of the ancient Aztecs, and it is likely that throughout America numerous counterparts could be discovered.

D. G. Brinton.

University of Pennsylvania.

NOTES ON INORGANIC CHEMISTRY.

Léon Franck details in the Bulletin of the French Chemical Society some interesting experiments on the formation of metallic sulfids by mechanical action. When a mixture of fine aluminum powder and flowers of sulfur is rubbed between two sheets of paper, hydrogen sulfid is evolved, owing to the formation of aluminum sulfid and its subsequent decomposition. The same reaction takes place between magnesium powder and flowers of sulfur. If an aluminum plate be rubbed with flowers of sulfur, or even with vulcanized rubber, the odor of hydrogen sulfid is distinctly perceptible. With those metals whose sulfids are not decomposed in the air the reaction is different. When a plate of silver is rubbed with flowers of sulfur it gradually darkens, owing to the formation of silver sulfid, and if the action is continued, little prominences of silver sulfid are formed, which can be removed by a knife. Copper and lead give the same reaction as silver.

This reaction corresponds to the well known darkening of silver coins when carried in the pocket with sulfur matches. In the case of blackening of silver spoons by eggs the reaction is somewhat different, as the sulfur is in combination and in solution. The layer of sulfid must in this case be exceedingly thin, for silver spoons which have been used sometimes for more than a generation have been cleaned again and again, perhaps weekly, each time the layer of sulfid being rubbed off, and yet the spoons show apparently little diminution of weight.

In the *Comptes Rendus*, Léon Lémal describes the coloring of glass by the direct penetration of metals or metallic salts, analogous to the cementation process of steel making. If glass is covered with a silver salt, even in small quantity and heated to 500°–550°, on cooling it shows a

yellow to orange-red color, according to the length of time of heating. The depth of penetration of the color depends upon the duration of the reaction. Such glass is yellow by transmitted light, but by reflected light shows a yellowish-green to violet-blue fluorescence. By using a silver photographic plate on red glass colored with copper, it is possible to obtain a picture, visible by reflected light, but not by transmitted light, since the yellow of the picture is obscured by the red glass. Gold, copper and iron give results similar to silver; indeed, all metals experimented with, except manganese, were absorbed by the glass imparting to it color.

A CONTRIBUTION to the effect of light upon the union of hydrogen and chlorin is made by A. Gautier and H. Hélier in the *Comptes Rendus*. A mixture of carefully purified chlorin and hydrogen was kept in sealed tubes in absolute darkness for over fifteen months. No trace of hydrochloric acid was found, and the result was the same, whether the mixture was dry or moist. Similar experiments were tried, but the mixtures were exposed to the light of a candle, four meters away from the tube, and again one meter away. At the end of ten days it was found there had been no hydrochloric acid formed, showing that sunlight, or some source of light containing the more refrangible rays of the spectrum, is necessary for the union of hydrogen and chlorin at ordinary temperatures.

J. L. H.

SCIENTIFIC NOTES AND NEWS.

AN INTERNATIONAL ASSOCIATION.

THE meeting of the British Association in Canada in 1884 was thought a favorable opportunity for the proposal of an International Scientific Association, and the plan was editorially commended in this JOURNAL and supported by Professors Newcomb, Hunt, Minot and other American men of science. At that time Mrs. Elizabeth Thompson gave a fund to be administered by the Association when organized. The second meeting of the British Association in America and the plans for an exchange of courtesies between it and the American Association and between the British and French Associations in 1899, together with the development of international congresses for the separate sciences, seemed to make it desirable again to call attention to the importance of an international association for the advancement of science, and this was done in an article published in the issue of this JOURNAL for October 9, 1896.

The plan was approved in editorial articles in the *Scientific American* and *Appleton's Popular Science Monthly* and was quoted and discussed in foreign scientific journals. For reasons which we need not repeat, the advantages of an international conference seem to outweigh the difficulties, and we should like to see steps taken at the meetings of the American and British Associations for the organization of a congress to meet in 1900. Should it, however, be thought that the time has not yet come, then we should be glad to see the National Associations undertake in alternation to give their meetings an international character. This will to a certain extent be accomplished this year by the British Association. Arrangements should be made next week to secure the representation of foreign associations and societies by delegates at the next meeting of the American Association on the occasion of its fiftieth anniversary.

THE NEW TARIFF LAW.

THE tariff bill, now printed, fortunately contains none of the provisions inimical to science and education, against which we protested when the bill was first presented to the House of Representatives. The present bill does not materially alter the regulations in force during the last four years. The sections of the free list which concern apparatus, books, etc., read as follows:

Philosophical and scientific apparatus, utensils, instruments and preparations, including bottles and boxes containing the same, specially imported in good faith for the use or by the order of any society or institution, ncorporated or established solely for religious, philosophical, educational, scientific or lit-

erary purposes, or for the encouragement of the fine arts, or for the use or by order of any college, academy, school or seminary of learning in the United States, or any State or public library, and not for sale, subject to such regulations as the Secretary of the Treasury shall prescribe.

Books, maps, music, engravings, photographs, etchings, bound or unbound, and charts, which shall have been printed more that twenty years at the date of importation, and all hydrographic charts and scientific books and periodicals devoted to original scientific research, and publications issued for their subscribers or exchanges by scientific and literary associations or academies, or publications of individuals for gratuitous private circulation, and public documents issued by foreign governments.

Books and pamplets printed exclusively in languages other than English; also books and music, in raised print, used exclusively by the blind.

Books, maps, music, photographs, etchings, lithographic prints, and charts, specially imported, not more than two copies in any one invoice, in good faith, for the use or by order of any society or institution incorporated or established solely for religious, philosophical, educational, scientific, or literary purposes, or for the encouragement of the fine arts, or for the use or by order of any college, academy, school, or seminary of learning in the United States, or any State or public library, and not for sale, subject to such regulations as the Secretary of the Treasury shall prescribe.

It may also be noted that the free list includes specimens of natural history, when imported for scientific public collections and not for sale, and wild animals imported for zoological gardens. Personal effects of travellers purchased abroad are limited to the value of $100, but professional books, implements, instruments and tools of trade, occupation or employment, in the actual possession at the time of persons arriving in the United States are free of duty.

THE GOLD RESOURCES OF THE YUKON REGION.

THOSE interested in the gold resources of the Yukon region in Alaska should secure, from the Geological Survey, the report of the expedition made under the direction of Mr. J. E. Spurr last summer, a brief account of which was published in this JOURNAL on November 27, 1896. The party crossed the Chilkoot Pass, about the middle of June, to the headquarters of the Yukon, and proceeded down the river to the chief gold-bearing localities. The principal producing districts, those of Forty-Mile Creek and Birch Creek, were thoroughly explored, as well as other less important localities. The party then continued down the Yukon, examining the younger sedimentaries which overlie the gold-bearing formation, as far as Nulato. One of the principal results of the expedition was the recognition of the gold-bearing rocks from which the gold in the river gravels is derived. These gold-bearing rocks constitute a distinct broad belt running northwest into Alaska from British territory. They are in their lower portions schists and gneisses, with intrusive rocks, and in their upper portion somewhat altered sedimentaries. They are all older than Carboniferous, for the Carboniferous and younger rocks overlie them on both sides of the gold-bearing belt. In this belt the gold occurs partly in quartz veins, partly in deposits formed along shear-zones; in both occurrences it is contained in pyrite, and becomes free on weathering. The quartz veins are distinctly older than the shear-zone deposits, and were formed before the alteration of the enclosing rock to a schist; they have, therefore, partaken of this shearing, and have been broken and sheared so that they are typically non-persistent. The deposits along shear-zones are, however, of later date than the shearing, and can be continuously followed. The younger beds which overlie the gold-bearing belt consist in part of conglomerates, and some of these conglomerates are fossil placers, which give promise of being productive.

GENERAL.

THE French Association for the Advancement of Science is holding its annual meeting simultaneously with that of the American Association. The meeting is at Saint Étienne, under the presidency of M. Marey, the eminent physiologist.

AT a meeting summoned by the Lord Provost of Glasgow, and attended by representatives from the magistrates, the University, St. Mungo's College, the Philosophical and other scientific societies, it was unanimously decided to invite the British Association to meet in Glasgow in the autumn of 1901.

THE German Botanical Society will this year hold its annual meeting at Brunswick, beginning September 21st, in conjunction with the sixty-ninth meeting of the German Society of Men of Science and Physicians.

WE have published programs of the meeting of the British Medical Association at Montreal, beginning August 31st. The Sections of the Association devoted to scientific subjects will undoubtedly attract to Montreal many of the British and American men of science attending the Toronto meeting of the British Association. The annual business meeting of the Medical Association was held in London on July 27th and 28th, and the reports of the Council and of the committees have been published in the *British Medical Journal*, the official organ of the Association, to which journal its great success is in large measure due. The membership of the Association is now 16,955, and the revenue for the past year amounted to $190,000.

WE are requested by the Secretary of the American Society of Naturalists to publish the following communication, read at the last meeting of the Society:

TORONTO, December 24, 1896.

To the Secretary of the American Society of Naturalists.

DEAR SIR: The Local Executive Committee of British Association respectfully calls attention to the fact that the next meeting of the Association will be held in Toronto, August 18–25, and the members of the American Society of Naturalists are invited to become members of the Association for the occasion.

A large number of representative British scientific men have thus early promised to attend and the Local Committee are endeavoring to secure the attendance also of large numbers of distinguished Continental (European) scientific men at the meeting.

Permit me to assure the members of the American Society of Naturalists that everything will be done to make their visit to Toronto an extremely pleasant one.

Yours sincerely,

A. B. MACALLUM,
President of the Local Executive Committee.

THE daughters of Joseph Henry, the first Secretary of the Smithsonian Institution, have presented to the Institution for the National Museum an interesting collection of electrical models devised by Henry, and of decorations, etc., conferred upon him.

THE late Sir Augustus Wollaston Franks, formerly keeper of British and mediæval antiquities of the British Museum, has bequeathed to the Museum his valuable collection of works of art, ornaments and curiosities.

IT is proposed to collect a fund for a memorial at Glasgow to John and William Hunter, the great physiologists. An executive committee for this purpose was appointed at a public meeting recently convened at Glasgow. The movement originated with the late Dr. Mather, and Mrs. Mather, who was present at the meeting, stated that she had a sum of £850 with which to head the subscription list.

PROFESSOR EDGAR MCCLURE, of the Oregon State University, fell 300 feet over a precipice on the Muir Glacier while descending Mount Rainier on July 27th and was killed. Two other members of the Mazama Mountain Climbing Club, Mr. George Rogers and Mr. H. Ainslee, of Portland, Ore., fell into a crevasse on Mt. Rainier forty feet deep, and the former may not recover from his injuries.

SIR JOHN BUCKNELL, F. R. S., the author of important contributions to neurology and insanity, formerly editor of the *Journal of Mental Science* and one of the editors of *Brain* and of the *British Medical Journal*, died at Bournemouth on July 20th, aged 79 years.

MR. A. J. MUNDELLA, the English statesman, who as Vice President of the Council on Education and President of the Board of Trade took an active interest in science and education, died on July 21st, aged 72 years. He was a fellow of the Royal Society and of the Royal Statistical Society.

WE regret also to announce the deaths of the following men of science: Professor Arminio Nobile, professor of geodesy in the University of Rome; Professor Oscar Boer, of Berlin, known for his work on infectious diseases, and Professor Johann Ritter von Leich, formerly dean of the medical faculty of the University of Vienna, at the age of eighty-four.

DR. RADCLIFFE'S trustees have decided to appoint to the post of Radcliffe Observer at Oxford, vacant by the death of the late Mr. E.

J. Stone, Dr. Arthur A. Rambaut, of Dunsink Observatory, Dublin. Dr. Rambaut is Andrews professor of astronomy in the University of Dublin and Royal Astronomer of Ireland.

DR. BRUNO HOFER, docent in zoology at the University of Munich, has been appointed director of the recently established institute for the study of diseases of fishes.

AT a recent meeting of the Council of the British Institute of Preventive Medicine, Dr. Allan Macfadyen was appointed Director of the Institute.

M. GAYON has been elected a member of the Paris Academy of Sciences in the room of the late Professor Hellriegel.

THE official delegates to the recent International Library Conference were as follows: *France*, M. Omont; *Germany*, Dr. Milkau; *Italy*, Signor Biagi; *Sweden*, Dr. Lunstedt; *Hungary*, Dr. Erdelyi; *Japan*, Enjiro Yamazo; of the Anglo-Saxon race—*Great Britain*, Sir Horace Walpole, Mr. C. H. Tawney; *United States*, Dr. Justin Winsor, Mr. Melvil Dewey, Mr. Herbert Putnam; *Canada*, Mr. A. D. de Celles; *New South Wales* and *Victoria*, Mr. H. C. L. Anderson; *New Zealand*, Mr. W. P. Reeves; *Jamaica*, the Rev. Dr. Gillies.

THE chairmen of the committees of the House of Representatives having more or less connection with scientific subjects, appointed by the Speaker before the adjournment of the House, are as follows: Coinage, Weights and Measures, Mr. Stone, of Pennsylvania; Agriculture, Mr. Wadsworth, of New York; Public Lands, Mr. Lacey, of Iowa; Railways and Canals, Mr. Chickering, of New York; Manufacturers, Mr. Faris, of Indiana; Mines, Mr. Grosvenor, of Ohio; Education, Mr. Growe, of Pennsylvania; Patents, Mr. Hicks, of Pennsylvania.

PROFESSOR CHAS. D. WALCOTT, Director of the U. S. Geological Survey, has gone west to inspect and direct the field work of his bureau, more especially the survey and examination of the forest reserves, for which Congress, at its last session, made a special appropriation of $150,000. Mr. Walcott expects to be absent until October. In his absence, Colonel Rizer, the Chief Clerk, is acting as Director.

MR. GEO. H. ELDRIDGE, of the U. S. Geological Survey, has gone to Utah, at the instance of the Secretary of the Interior, to reexamine, in greater detail than was possible at the time of his reconnaissance a year ago, the deposits of Gilsonite and allied Hydrocarbons within the Uncompahgre and Ute Indian reservations.

THE daily papers report that Professor William Libbey, on July 23d, succeeded in scaling the 'Mesa Encantada,' near the Indian village of Acoma, New Mexico. By means of a cannon and rocket apparatus similar to that used by life-savers, a cord was shot over the tableland, and the ropes required in making the ascent were pulled up. All that was found on top which indicated that the tableland might have been inhabited was a pile of rocks which looked as if it had been erected by man. Professor Libbey is said to be convinced that the legends which made the place the site of an ancient village are unfounded.

THE London correspondent of the *Evening Post* cables that the Egyptian government is increasing the staff engaged on the geological survey of upper Egypt for the coming winter so as to keep five distinct parties at work. The survey may possibly develop in time into a scientific bureau of Egyptian natural history. A vote of 100,000 francs has been passed by the French Chamber of Deputies for explorations in Persia this autumn. The convention signed by the Shah gives a monopoly of researches throughout Persia to the French, the conditions being that one-half of the objects found shall pass to the state. M. De Morgan, well known through his investigations in Egypt, will conduct the operations.

MR. GEORGE MURRAY and Mr. V. A. Blackman have gone to the West Indies for the purpose of studying the Plant-Plankton of the Atlantic ocean.

ADVICES from Sydney state that the search party under the leadership of Mr. L. A. Wells has found the bodies of Charles Wells and George L. Jones, who, it will be remembered, were lost nearly two years ago from the main body of the Calvert expedition, engaged in the exploration of West Australia.

GREAT BRITAIN has accepted the proposal of the United States for an international conference on the question of pelagic sealing in the Bering Sea, to be held in Washington during the coming autumn.

THE fourth congress for the study of tuberculosis will be held at Paris during the last week of July, 1898, under the presidency of M. Nocard. The following four questions are proposed for discussion: Sanitaria for consumptives, serums and toxins, the X-rays in diagnosis and treatment, and tuberculosis in the lower animals.

IN connection with the Brussels Exposition, there will be held, from August 9th to 14th, a Congress of Hygiene and Medical Climatology of Belgium and the Congo.

AT the last monthly general meeting of the London Zoological Society it was reported that the additions to the Society's menagerie during the month of June had amounted to 178. Special attention was called to two fine adult King Penguins (*Aptenodytes pennanti*) purchased on June 23d, and a young female Orang-outang (*Simia sotyrus*), brought home from Sumatra, and presented by Dr. H. Dohrn, on June 30th.

MRS. VIRGINIA MONROE has given $30,000 to the Pequot Library Association, the building of which was the gift of the late Albert B. Monroe.

MR. ANDREW CARNEGIE has offered the town of Stirling, Scotland, the sum of £6,000 for a public library building.

THE issue of *Nature* for July 15th contains an appreciative review, by Professor A. G. Greenhill, of the text-book of higher mathematics edited by Professors Merriman and Woodward: "This is a style of mathematical treatise to which we are not accustomed in this country, from the luxury of the print and size of page, as well as for the refreshing novelty and interest of the contents. Till recently it was thought that the study of mathematics was not likely to flourish in America as *trop vieux jeu* by the side of the new physical and biological sciences. To-day, however, it is the American student who is the most enthusiastic follower of recent mathematical development, while we in this country are being left far behind. * * * * * The account, given by the editors in the preface, of the work expected of the average American student, shows that the standard of requirement is much higher than in this country and not hampered by traditional prejudice."

THE anatomical departments of the *Journal of Anatomy and Physiology* will hereafter be edited by Professors Turner, MacAlister, Cunningham and Thane. Professor M'Kendrick will continue to edit the physiological department.

UNIVERSITY AND EDUCATIONAL NEWS.

THE University of London Bill has been introduced into the House of Lords by the Duke of Devonshire and has been read for the second time.

THE United States Circuit Court at Baltimore, on July 29th, handed down a decision that the Johns Hopkins University and other holders of first preferred 6 per cent. stock of the Baltimore and Ohio Railroad are not preferred creditors. The trustees of the University hold nearly $2,000,000 of the preferred stock, bequeathed by the founder of the University, the late Johns Hopkins, and this decision, if upheld by the higher Courts, will seriously and permanently curtail the income of the University.

As was stated in this JOURNAL last autumn, it is proposed to draw up plans for buildings such as the University of California hopes ultimately to erect. We fear, however, that the sum of $4,000,000, which the daily papers report to have been subscribed for the erection of these buildings, has not as yet been secured.

IT is reported in the daily paper that Dr. E. Benjamin Andrews, who resigned the presidency of Brown University for reasons given in our last issue, has accepted the presidency of a new 'university' to be founded by Mr. John Brisben Walker, proprietor and editor of the *Cosmopolitan Magazine*, and to be known as the 'Cosmopolitan University.' It is to be modelled after the Chautauqua School and to be conducted by correspondence.

PROFESSOR HENRY KRAEMER, of the Northwestern University, has been called to the chair of botany and microscopy in the Phila delphia College of Pharmacy, and Dr. Albert

Schneider, Ph.D. (Columbia), has been called to the chair in Northwestern University vacant through the resignation of Professor Kraemer.

Dr. L. Schlesinger, of Bonn, has been appointed full professor of mathematics at Klausenburg; Dr. Detmer, associate professor of botany in the University of Jena, has been promoted to a full professorship; Dr. Lassar Cohn, professor of chemistry in the University at Königsberg, has been elected director of the Liebig Akademie of Munich; Dr. A. O. Kihlman has been appointed associate professor of botany at Helsingfors, and Dr. G. J. Ptaschicky, professor of zoology in St. Petersburg; Dr. F. v. Luschan, docent in the University of Berlin, has been promoted to a professorship of anthropology; Dr. Seelhorst, director of the Agricultural Experiment Station at Göttingen has accepted a professorship in the Agricultural College at Hohenheim.

DISCUSSION AND CORRESPONDENCE.

COLOR STANDARDS.

It is a matter for congratulation that the subject of color standards and definitions has been brought before the public for discussion in Science* Education in any branch of knowledge becomes simple and successful in proportion as its terminology is definite and intelligible. It would be quite interesting to set forth the plans that have been offered for obtaining color standards; one proposes to take an orange as the type of that color, and in like manner to let a lemon, an olive, etc., be the ultimate definition of those hues. One has even suggested a collection of wines of various colors as standards, and the matching of other colors by mixing the wines, an operation as dangerous as it is unscientific.

In the search for standards we must first be able to define completely a colored surface; not by saying that it resembles or differs to a certain extent from some other arbitrary surface, but it must be defined in terms of certain invariable and readily reproducible standards.

To describe completely a surface we must give value to four factors which go to affect the impression which it produces upon the normal observer: First, the predominating wave-length or wave-lengths of the light coming from it; second, its total luminosity, as compared with some standard; third, its saturation, or the ratio of the colored light to the total luminosity; fourth, its texture.

* See article in Science, July 16, p. 89.

The matter of texture may be eliminated by placing the surface far enough from the eye, or, better, by rotating it so rapidly that the eye cannot distinguish the texture; consequently a standard of texture is unnecessary. A standard of total luminosity is easily obtained by holding a cold surface over burning magnesium or zinc; the coating of oxide thus produced has been adopted as 'white' by Rood, Mayer and others. In other words, the luminosity of such a surface is taken as 100 %. A box about five feet in length and one in cross-section, lined with black velvet and provided with an opening about four inches in diameter in one end, when so mounted that light cannot shine directly into the opening, will furnish an admirable standard black, or 0 % luminosity. Between these two extremes fall all surfaces not incandescent. White cardboard and lamp-black form very convenient 'practical units,' and their relation to the standards can at any time be easily and accurately determined. The question of saturation, or the ratio of the energy of the predominating characteristic wave-lengths to the total visible energy, is serious. In fact, for the present we must be satisfied to agree upon some temporary standards which may ultimately be absolutely determined.

As to the predominating or characteristic wave-length or wave-lengths we might, of course, refer everything to the spectrum and define by it directly, but it would be a very elaborate and inconvenient method. It is, however, customary to adopt a few typical wave-lengths and define by combinations of these. Theoretically three such colors are sufficient, but practical convenience makes it desirable to have five or six. Then a mixture of these, with the addition of black and white when necessary, enable the observer to match any color, shade, tint or hue.

What shall govern the choice of the five or six working standards? Of course, we expect red, green and blue; probably yellow, and pos-

sibly orange and violet. At first the scientific method would seem to be to choose from the spectrum itself and locate those colors ideally, but we wish concrete surfaces of paper or similar material for our working standards, and if we choose our colors thus can we match them in practice? Chromolithography can do wonders and can nearly match a spectrum color. The objection, however, to such working standards is that each lithographer, and indeed the same one at different times, will succeed to different degrees, so that a slight variation in color, luminosity and saturation is inevitable.

Moreover, practically all the lithographic inks used in such work will fade, and fade surely and badly, a fatal objection to their use as standards. Another way to choose the working colors is to have in mind the pigment to be used in representing the color, as well as the particular wave-length desired.

It was the apparent advantages of the latter method, as well as the advice of good authorities, which led us to follow it in the choice of our working standards when we were asked to prepare the material in the 'Standard Dictionary.' In our choice we were influenced by the following considerations: Emerald green (Paris green) is of the desirable color, is very uniform and is easily obtained; similar advantages recommend artificial ultra-marine blue. For a red, evidently a vermilion should be taken, and in selecting 'English vermilion' we may have erred, but believe it the most uniform and best suited. Mineral orange seemed very nearly identical in different samples, and was adopted since its color was that desired. As to chrome yellow it may be very truly urged that there are great variations, but when the samples are chosen by wave-length the character of the yellow is identical. The lack of a good, permanent violet pigment, as well as the apparent lack of the necessity of having a violet standard induced us to omit it. These pigments can be obtained everywhere, and for most purposes true enough to wave-length. They fade but slightly, if at all, and when mixed with thick gum arabic solution and applied like an oil paint to completely cover the surface their total luminosity and saturation is always practically the same. They thus furnish working standards which can be reproduced by anybody in any part of the world with great accuracy if necessary. Together with white cardboard and lamp black carried in shellac they enable an observer to produce practically any color, shade, hue or tint, by combining them as Maxwell disks.

Other pigments, other colors, may finally prove more worthy of general and final adoption, but it seems to us that the considerations which influenced us most seriously influence the final selection.

No doubt Mr. Pillsbury regretted that his system was not adopted for the 'Standard Dictionary', but that should not have induced him to insinuate that we copied his system, or to refer to a typographical error as 'an unintentional blunder.' We have no desire to belittle the work of Milton Bradley or Mr. Pillsbury, for they are doing much for the introduction of scientific methods into color study, but it did not seem best to us to attempt to define all colors, using only two colored discs at a time, and we do not believe that any lithographed surfaces should be adopted as ultimate standards, even though they may prove best adapted to educational purposes.

W. HALLOCK,
R. GORDON.

THE TERM 'INTERNAL SECRETIONS.'

TO THE EDITOR OF SCIENCE: At the beginning of his interesting paper on 'The Physiology of Internal Secretions,' SCIENCE, No. 132, Dr. Howell says: "We owe the term 'internal secretions' to Brown-Séquard, by whom it was first used in published communications dating from 1891." It may be worth while to note that Claude Bernard in his famous 'Rapport sur les progrès et la marche de la physiologie générale en France,' 1867, says, at page 73, "La cellule sécrétoire, au contraire, attire, crée et élabore en elle même le produit de sécrétion, qu'elle verse soit au dehors sur les surfaces muqueuses, soit directement dans la masse du sang. J'ai appelé *sécrétions externes* celles qui s'écoulent en dehors, et *sécrétions internes* celles qui sont versées dans le milieu organique intérieur."

C. B. DAVENPORT.

MUS. COMP. ZOOL., July 26, 1897.

SCIENTIFIC LITERATURE.

Vorlesungen über die Elektromagnetische Theorie des Lichts, von H. VON HELMHOLTZ. Herausgegeben von ARTHUR KÖNIG und CARL RUNGE. Hamburg and Leipzig, Verlag von Leopold Voss. 1897.

Since the experiments of Hertz proved the existence of electro-magnetic waves propagated through dielectrics, the attention of an increasing number of physicists has been turned to the careful study of Maxwell's 'Electro-magnetic Theory of Light,' and the belief has become practically universal that this theory, in its general outlines at least, corresponds closely to physical facts. Several hundred important papers on matters more or less nearly related to the theory have been published during the last ten years, and the results of investigation have been made fairly accessible to students through the books of Boltzmann, Drude, Hertz, Poincaré, J. J. Thomson and others. When, however, a great university teacher, who has had much to do with the creating of a new branch of science, writes a systematic treatise on the subject for the use of his pupils, the event must always be of interest to the scientific world, and this is especially true when the subject is so important and in some respects still so abstruse as the Electro-magnetic Theory of Light is. The lectures, which are now published under the editorship of Professors König and Runge, were delivered substantially in their present form by Helmholtz in the Winter Semester of 1892–93. An accurate stenographic report of the words of the lecturer was made by Dr. Borchardt, and this report, with slight editorial changes, made in part by Helmholtz himself, and with some additions, made by his directions, to the chapters on Geometrical Optics, is reproduced in a beautifully printed royal octavo volume of about 370 pages.

The lectures begin with a short account of the Newtonian and the Huyghenian Theories of Light and of the objections to each of them. A discussion of the conditions which the propagation of plane longitudinal and transverse waves through elastic media presupposes, makes clear the necessity of ascribing to the ether the elastic properties of a solid, if it is to transmit transverse vibrations mechanically, and leads naturally to a preliminary presentation of Maxwell's theory based on Faraday's conceptions of magnetic and dielectric polarizations. After this introduction, a long chapter is devoted to a very simple and clearly written but very complete discussion of electro-magnetic oscillations, intelligible to any person who already has a fair knowledge of the meaning of polarization and of the differences between 'real,' 'apparent' and 'induced' magnetic and electric densities. This discussion calls attention anew to the fact that the nomenclature and the notation of the subject are in a very unsatisfactory state. Helmholtz himself sometimes defined inductivity so as to make that of the ether 1 and sometimes so as to make it 4π, and the editors of these lectures were obliged to change the notation in some places so as to make the whole book consistent. The subject will be needlessly difficult for students so long as different writers give the name 'polarization,' without any modifying clause, to three very different quantities.

In transforming Maxwell's equations for electro-magnetic fields, Helmholtz treats the principles first elucidated in his own great paper on Vortex Motion, published in 1858, simply as analytical devices useful in integrating differential equations of a certain form. Neither here nor elsewhere in the book does the lecturer make any reference to his own contributions to the subject. In the third chapter the properties of spherical waves are studied in detail, and Huyghens's Principle is put into a very satisfactory shape by the help of an extended form of Green's Theorem in which the time and the space coordinates appear as independent variables. This makes it possible to treat Diffraction, Interference and Geometrical Optics in the next two chapters very much as they are treated in older books on the Undulatory Theory of Light.

The final chapter is devoted mainly to Polarization, Absorption and Dispersion, and is especially interesting since it gives the author's theory of Dispersion in its latest form. This theory assumes that every molecule of matter is made up of two ions, one charged positively and the other negatively. The amounts of these two charges in any molecule are very large and numerically equal, and each depends only upon

the valency of the ion in that molecule and not upon the chemical nature of the ion. Under the influence of electric force, the ions in any molecule may be made to take up a new position while their center of mass remains fixed. If the force varies periodically, a part of the energy of the field is used in keeping up the oscillations of the ions about this center of gravity in the face of heat losses. Helmholtz applies Hamilton's Principle to the equation of energy and arrives at results which correspond fairly well to observed facts.

The whole book is written in delightfully simple language and seems to be quite free from typographical errors. We merely note, in passing, that George Green held a fellowship in Cambridge from 1839 until his death in 1841, but never a professorship there. These lectures form one of a projected set of six volumes of Helmholtz's Vorlesungen über Theoretische Physik which will be extremely useful to students of physics all over the world.

Harvard University. B. O. Peirce.

THE AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

GENERAL PROGRAM.

The regular meeting of the Council will be at the Hotel Cadillac (hotel headquarters) at noon on August 7th.

On Monday, August 9th, at 9 a. m., the Council will meet in the Council Room, Central High School.

The first General Session of the Association will be held at 10 a. m., in the Auditorium of the Central High School. Owing to the death of Professor Edward D. Cope, the President of the Association, Professor Theodore Gill, of Washington, D. C., as Senior Vice-President, will call the meeting to order and introduce the President-elect, Professor Wolcott Gibbs, of Newport, R. I. Addresses of welcome will be made by his Honor Mayor William C. Maybury and Hon. Thomas W. Palmer, and President Gibbs will reply. Announcements by the General, Permanent and Local Secretaries will then be made.

The Addresses of the Vice-Presidents will be given in the afternoon as recorded below. In the evening Professor Theodore Gill, of Washington, D. C., will give a memorial address on the life and work of the late President, Professor Edward D. Cope. Following this address there will be a reception given by the citizens of Detroit.

On Tuesday, Wednesday, Thursday and Friday the regular meetings of the Council will be held at 9 a. m. and of the general session at 10 a. m., followed in the mornings and afternoons by the meetings of the sections.

On Friday morning officers will be elected and an agreement reached on the place of meeting for 1898, the fiftieth anniversary of the Association. The concluding exercises and adjournment of the sections of the Association and a social reunion and reception by the Ladies' Reception Committee will take place in the evening.

On Saturday there will be an excursion to Ste. Claire Flats.

It is expected that the members of the Association at Detroit will go in a body to Toronto to join in welcoming the members of the British Association to America. For this purpose special rates will probably be secured by steamer and train from Detroit to Toronto.

The programs of the sections are given below. These are as complete as possible up to the time of issue of this number of Science, but other papers will be presented at the meeting and entered on the daily programs.

SECTION A.—MATHEMATICS AND ASTRONOMY.

Address of the Vice-President: A Chapter in the History of Mathematics. By Professor W. W. Beman, University of Michigan, Ann Arbor, Mich.

1. A Problem in Substitution-groups. By Dr. G. A. Miller, Ann Arbor, Mich.

2. Continuous Groups of Spherical Transformations in Space. By Professor H. B. Newson, Lawrence, Kans.

3. The Treatment of Differential Equations by Approximate Methods. By Professor W. F. Durand, Ithaca, N. Y.

4. Commutative Matrices. By Professor J. B. Shaw, Jacksonville, Ill.

5. On the Theory of the Quadratic Equation. By Professor A. Macfarlane, Lehigh Univ., South Bethlehem, Pa.

6. A New Principle in solving certain Linear

Differential Equations that occur in Mathematical Physics. By Professor A. Macfarlane, Lehigh Univ., South Bethlehem, Pa.

7. Condition that the Line common to n-1 planes in an n-space may lie on a given Quadric Surface in the same space. By Dr. Virgil Snyder, Ithaca, N. Y.

8. The Psychology of the Personal Equation. By Professor T. H. Safford, Williamstown, Mass.

9. Compound Determinants. (Preliminary Communication.) By Professor W. H. Metzler, Syracuse, N. Y.

10. Waters within the Earth. By W. S. Auchincloss, C.E., Philadelphia, Pa.

11. On the Secular Motion of the Earth's Magnetic Axis. By Dr. L. A. Bauer, Univ. of Cincinnati, Cincinnati, O.

12. Simple Expressions for the Diurnal Range of the Magnetic Declination and of the Magnetic Inclination. By Dr. L. A. Bauer, Univ. of Cincinnati, Cincinnati, O.

13. The Theory of Perturbations and Lie's Theory of Contact-transformations. By Dr. E. O. Lovett, Baltimore, Md.

14. On Rational Right Triangles. No. I. By Dr. Artemas Martin, U. S. Coast Survey, Washington, D. C.

15. Some Results in Integration expressed by the Elliptic Integrals. By Professor James McMahon, Cornell Univ., Ithaca, N. Y.

16. Modification of the Eulerian Cycle due to Inequality of the Equatorial Moments of Inertia of the Earth. By Professor R. S. Woodward, Columbia Univ., New York.

17. Integration of the Equations of Rotation of a Non-rigid Mass for the case of Equal Principal Moments of Inertia. By Professor R. S. Woodward, Columbia Univ., New York.

18. General Theorems concerning a certain class of Functions deduced from the properties of the Newtonian Potential Function. By Dr. J. W. Glover, Ann Arbor, Mich.

19. The Importance of Adopting Standard Systems of Notation and Coordinates in Mathematics and Physics. By Professor Frank H. Bigelow, U. S. Weather Bureau, Washington, D. C.

20. A Remarkable Complete Quadrilateral among the Pascal Lines of an Inscribed Six-point of a Conic. By Professor R. D. Bohannan, Columbus, Ohio.

JAMES MCMAHON,
Secretary of the Section.

CORNELL UNIVERSITY.

SECTION B.—PHYSICS.

Address of the Vice-President: Long Range Temperature and Pressure Variables in Physics. By Dr. Carl Barus, Brown University, Providence, R. I.

1. Screening Effects of Induced Currents in Solid Magnetic Bodies in an Alternating Field. By Mr. Charles P. Steinmetz, General Electric Company, Schenectady, N. Y.

2. The Design, Construction and Test of a 1250 Watts Transformer. By Professor Henry S. Carhart, Univ. of Mich., Ann Arbor, Mich.

3. Electrolytic Action in a Condenser. By Dr. K. E. Guthe, Instructor in Physics, Univ. of Mich., Ann Arbor, Mich.

4. On the Velocity of Light in a Magnetic Field. By Professor E. W. Morley, Cleveland, Ohio; Professor H. T. Eddy, Minneapolis, Minn., and Professor D. C. Miller, Cleveland, Ohio.

5. The Magnetic Survey of Maryland. By Dr. L. A. Bauer, Univ. of Cincinnati, Cincinnati, Ohio.

6. The Transmission of Radiant Heat by Gases at Varying Pressures. By Mr. Charles F. Brush, Cleveland, Ohio.

7. On the Rate at which Hot Glass absorbs Superheated Water. By Professor Carl Barus, Brown Univ., Providence, R. I.

8. A New Method of determining the Specific Heats of Liquids. By Robert L. Litch, A.M., Bethlehem, Pa.

9. On the Coefficient of Expansion of Certain Gases. By Professor Edward W. Morley, Cleveland, Ohio, and Professor Dayton C. Miller, Cleveland, Ohio.

10. The Effect of Heat on the Elastic Limit and Ultimate Strength of Copper Wire. By Professor Frank P. Whitman, Adelbert College, Cleveland, Ohio, and Mary C. Noyes, Ph.D., Lake Erie Seminary, Painesville, Ohio.

11. A Method of obtaining Capillary Canals of Specified Diameter. By Professor Carl Barus, Brown Univ., Providence, R. I.

12. Kites and their Use by the Weather

Bureau in Explorations of the Upper Air. By Professor C. F. Marvin, U. S. Weather Bureau, Washington, D. C.

13. Experiments upon the Acetylene-Oxygen Standard of Light. By Dr. Clayton H. Sharp, Cornell Univ., Ithaca, N. Y.

14. Arc Spectra. By Professor Arthur L. Foley, Univ. of Indiana, Bloomington, Indiana.

15. On the Brightness of Pigmented Surfaces under Various Sources of Illumination. By Professor Frank P. Whitman, Adelbert College, Cleveland, Ohio.

16. Note on the Construction of a Sensitive Radiometer. By Professor Ernest Fox Nichols, Colgate Univ., Hamilton, N. Y.

17. Photographs of Manometric Flames. By Dr. Edward L. Nichols, Cornell Univ., Ithaca, N. Y., and Professor Ernest Merritt, Ithaca, N. Y.

18. The Discharge of Electrified Bodies by X-rays. By Dr. C. D. Child, Cornell Univ., Ithaca, N. Y.

19. A Final Determination of the Relative Lengths of the Imperial Yard of Great Britain and the Meter of the Archives. By Professor William A. Rogers, Colby Univ., Waterville, Me.

20. The Electric Conductivity of certain Specimens of sheet Glass, with reference to their Fitness for Use in Static Generators. By Professor Dayton C. Miller, Case School of Applied Science, Cleveland Ohio.

21. Graphical Treatment of Alternating Currents in Branch Circuits in case of Variable Frequency. By Professor H. T. Eddy, Minneapolis, Minn.

22. On Simple Non-Alternating Currents. By Professor Alexander Macfarlane, Lehigh University, South Bethlehem, Pa.

23. Exhibition of Instruments for determining the Frequency of an Alternating Current. By Professor George S. Moler, Ithaca, N. Y., and Dr. Frederick Bedell, Cornell University, Ithaca, N. Y.

24. The predetermination of Transformer Regulation. By Dr. F. Bedell, Cornell University, Ithaca, N. Y.; Professor R. E. Chandler, Salem, Va., and Mr. R. H. Sherwood, Jr., Brooklyn, N. Y.

25. The effect of Pressure on the Wave-lengths of the lines of the Emission Spectra of the Elements. By Dr. W. J. Humphreys, Johns Hopkins University, Baltimore, Md.

26. A New Form of Coal Calorimeter. By Charles L. Norton, Massachusetts Institute of Technology, Boston, Mass.

27. Notes on the Recent History of Musical Pitch in the United States. By Professor Chas. R. Cross, Massachusetts Institute of Technology, Boston, Mass.

28. A New Form of Harmonic Analyzer. By Dr. Frank A. Laws, Massachusetts Institute of Technology, Boston, Mass.

29. A Comparison of Rowland's Thermometers with the Paris Hydrogen Scale, and the Corresponding Correction to his Value of the Mechanical Equivalent of Heat. By Dr. W. S. Day, Johns Hopkins University, Baltimore, Md.

30. The Determination of the Surface Tension of Water, and of Certain Aqueous Solutions, by means of the Method of Ripples. By Dr. N. Ernest Dorsey, Johns Hopkins University, Baltimore, Md.

31. The Series of International Cloud Observations made by the U. S. Weather Bureau, and their relation to Meteorological Problems. By Professor Frank H. Bigelow, U. S. Weather Bureau, Washington, D. C.

32. The Effects of Tension and Quality of the Metal upon the Changes in Length produced in Iron Wires by Magnetization. By Byron Briggs Brackett, Johns Hopkins University, Baltimore, Md.

33. Measurement of Small Gaseous Pressures. By Charles Brush.

Frederick Bedell,
Secretary of the Section.

Cornell University.

SECTION C.—CHEMISTRY.

Address of the Vice-President: Expert Testimony. By Professor W. P. Mason, Rensselaer Polytechnic Inst., Troy, N. Y.

The meetings of the Section will be held in conjunction with those of the *American Chemical Society.*

The papers of the Section will be divided into sub-heads with following committee in charge: A. B. Prescott, Organic Chemistry; W. A.

Noyes, Inorganic Chemistry; L. M. Dennis, Analytical Chemistry; H. W. Wiley, Agricultural Chemistry; Wm. McMurtrie, Industrial Chemistry.

The departments of Physical Chemistry and of Physiological Chemistry are not, as yet, filled.

Papers Presented to Secretary, A. A. A. S.

1. Recent Progress in Agricultural Chemistry. By Professor H. W. Wiley, Department of Agriculture, Washington, D. C.

2. Calculations of Calorimetric Equivalents of Agricultural Products from Chemical Analyses. By Professor H. W. Wiley and W. D. Bigelow, Department of Agriculture, Washington, D. C.

3. A Study of the Methods of Starch Determination in Agricultural Products. By Professor H. W. Wiley and W. H. Krug, Department of Agriculture, Washington, D. C.

4. The Action of Oxide of Manganese on Potassium Permanganate. By Chas. L. Reese, Baltimore, Md.

5. The Chemistry of Methylene. By Professor J. U. Nef, University of Chicago, Ill.

6. The Poisons of the Tuberculosis Bacillus. By Dr. E. A. de Schweinitz, Department of Agriculture, Washington, D. C.

7. The Action of Nitric Acid upon Aluminium and the Formation of Aluminium Nitrate. By Professor J. B. Stillman, Stevens Institute of Technology, Hoboken, N. J.

8. On the Action of Nitric Acid on Metals. By G. O. Higley.

9. Street Washings. By Professor L. P. Kinnicutt, Polytechnic Institute, Worcester, Mass.

10. Plastering and Mortar. By Professor L. P. Kinnicutt, Worcester, Mass.

11. Qualitative Analysis; a point in teaching that was not a full success. By Professor A. L. Green, Purdue University, Lafayette, Ind.

12. Annual Report on Indexing Chemical Literature. By Dr. H. C. Bolton, Washington, D. C.

13. On the Action of Sodium on Methylpropylketon and on Acetophenon. By Professor Paul C. Freer, University of Michigan, Ann Arbor, Mich.

14. On the Constitution of some Hydrazones. By P. C. Freer, Ann Arbor, Mich.

15. Position in the Periodic Law of the Important Elements found in Plant and Animal bodies. By Professor Harry Snyder, University of Minnesota, Minneapolis, Minn.

16. On two polymeric series of Phosphorus-Nitrogen compounds and on the Stereochemistry of Phosphorus and Nitrogen. By Dr. H. N. Stokes, United States Geological Survey, Washington, D. C.

17. The Chemical Composition of Cement Plaster. By Prof. E. H. S. Bailey, University of Kansas, Lawrence, Kan.

18. Recent Progress in Analytical Chemistry. By Professor L. M. Dennis, Cornell University, Ithaca, N. Y.

19. Alkyl Bismuth Iodides. By Professor A. B. Prescott, University of Michigan, Ann Arbor, Mich.

20. Kola tannin. By Professor A. B. Prescott, Ann Arbor, Mich.

21. A new form of Discharger for Spark Spectra of Solutions. By Professor L. M. Dennis, Cornell University, Ithaca, N. Y.

22. Recent Progress in Industrial Chemistry. By Professor Wm. McMurtrie, New York City.

23. On Solutions of Silicates of the Alkalies. By Dr. Louis Kahlenberg and A. T. Lincoln, University of Wisconsin, Madison, Wis.

Papers Presented to the Secretary of the American Chemical Society.

1. The Law of Solution. By Willis R. Whitney.

2. A New Thermostat. By Willis R. Whitney.

3. A Lecture Experiment illustrating the Law of Reactions of the First Order. By Willis R. Whitney.

4. Contributions to the Chemistry of Didymium. By L. M. Dennis and E. M. Chamot.

5. A Comparison of Methods for Determining Carbon Dioxide and Carbon Monoxide. By L. M. Dennis and C. G. Edgar.

6. Some New Compounds of Hydronitric Acid. By L. M. Dennis and C. H. Benedict.

7. A Preliminary Thermo-Chemical Study of Iron and Steel. By E. D. Campbell and Firman Thompson.

8. Further Study on the Influence of Heat-Treatment and Carbon upon the Solubility of Phosphorus in Steel. By E. D. Campbell and S. C. Babcock.

9. The Action of Certain Bodies on the Digestive Ferments. By Frank D. Simons.

10. The Decomposition of Heptane and Octane at High Temperatures. By A. W. Burwell.

11. Calculation of Calorimetric Values from Analytical Data. By H. W. Wiley.

12. The Chemical Composition of Cement Plaster. By E. H. S. Bailey.

13. Bacterial Products of Hog Cholera and Swine Plague. By E. A. de Schweinitz.

14. Detection of Foreign Fats in Butter and Lard. By C. B. Cochran.

15. Distillation in General. By Leon Labonde.

16. Apparatus for Photometric Determination of Lime and Sulphuric Acid. By J. I. D. Hinds.

17. The Composition of Humus. By Harry Snyder.

18. An Electrical Laboratory Stove. By M. D. Sohon.

P. C. Freer,
Secretary of the Section.
University of Michigan.

SECTION D.—MECHANICAL SCIENCE AND ENGINEERING.

Address of the Vice-President: The Groundwork of Dynamics. By Professor John Galbraith, School of Practical Science, Toronto.

1. Development of Engineering Industries by Scientific Research. By Professor W. S. Aldrich, W. Va. University, Morgantown, W. Va.

2. The Cement Laboratory as a Field for Investigation. By Professor F. P. Spalding, Cornell University, Ithaca, N. Y.

3. The Effect of Spark Losses on the Efficiency of Locomotives. By Professor W. F. M. Goss, Purdue University, Lafayette, Ind.

4. A New Apparatus for Testing Indicator Springs. By Professor M. E. Cooley, University of Michigan, Ann Arbor, Mich.

5. Flue Gas Analysis in Boiler Tests. By Professor D. S. Jacobus, Stevens Institute, Hoboken, N. J.

6. Effect of Temperature on the Strength of Steel. By Professor R. C. Carpenter, Cornell University, Ithaca, N. Y.

7. The Properties of Aluminum Alloys. By Professor R. C. Carpenter, Ithaca, N. Y.

8. Analysis of Composite, Concrete and Iron Beams. By Professor J. B. Johnson, Washington University, St. Louis, Mo.

9. Definition of Elastic Limit for Practical Purposes. By Professor J. B. Johnson, St. Louis, Mo.

10. Theories of some Planimeters without the aid of Calculus. By Professor Forest R. Jones, University of Wisconsin, Madison, Wis.

11. The Production of X-Rays by Means of the Planté Accumulator, in which voltage is chiefly concerned, the effect of current being largely eliminated (Illustrated by Stereopticon.) By Professor W. A. Rogers, Colby University, Waterville, Me.

12. A Universal Alternator for Laboratory Purposes. By Professor Henry S. Carhart, University of Michigan, Ann Arbor, Mich.

13. Calculation of the Energy Loss in Armature Cores. By Professor W. E. Goldsborough, Purdue University, Lafayette, Ind.

14. A New Formula for Determining the Width of Leather Belting. By Professor John J. Flather, Purdue University, Lafayette, Ind.

15. A Graphical Solution of Belting Problems. By Professor John J. Flather, Lafayette, Ind.

16. On Engineering Conditions connected with the Mounting of Instruments used on Eclipse Expeditions. By Professor David P. Todd, Amherst College, Amherst, Mass.

John J. Flather
Secretary of the Section.
Purdue University.

SECTION E.—GEOLOGY AND GEOGRAPHY.

Address of the Vice President: The Pittsburg Coal Bed. By Professor I. C. White, University of West Virginia, Morgantown, West Va.

1. Stylolites. By Professor T. C. Hopkins, State College, Centre Co., Pa.

2. A Suggestion in Regard to the Theory of Volcanoes. By Professor William North Rice, Wesleyan Univ., Middletown, Ct.

3. The Ores and Minerals of Cripple Creek, Colorado. By H. P. Parmelee, Charlevoix, Mich.

4. Observations on the Genus Barrettia. By Professor R. P. Whitfield, American Museum of Natural History, New York, N. Y.

5. Changes of Level in Mexico. By Dr. J. W. Spencer, Washington, D. C.

6. An Account of the Researches relating to the Great Lakes. By Dr. J. W. Spencer, Washington, D. C.

7. Lake Chicago and the Chicago Outlet. By Frank Leverett, U. S. Geological Survey, Denmark, Iowa.

8. The Lower Abandoned Beaches of Southeastern Michigan. By Frank B. Taylor, Fort Wayne, Ind.

9. Recent Earth Movement in the Great Lake Region. By G. K. Gilbert, U. S. Geological Survey, Washington, D. C.

10. Pre-glacial Topography and Drainage of Central-Western New York. By Professor H. L. Fairchild, University of Rochester, Rochester, N. Y.

11. Progress of Hydrographic Investigations by the U. S. Geological Survey. By F. H. Newell, U. S. Geological Survey, Washington, D. C.

12. The Geological Age and Fauna of the Huerfano Basin in Southern Colorado. By Professor Henry F. Osborn, Columbia University.

13. A Supplementary Hypothesis respecting the Origin of the American Loess. By Professor T. C. Chamberlin, University of Chicago.

Other papers will be read before the Geological Society of America.

C. H. Smyth, Jr.,
Secretary of the Section.

Hamilton College.

SECTION F.—ZOOLOGY.

Address of the Vice-President: The Spread of Species by the Agency of Man, with especial reference to Insects. By Professor L. O. Howard, Department of Agriculture, Washington, D. C.

1. On the Relationships of the Nematognaths. By Professor Theo. Gill, Columbian University, Washington, D. C.

2. Remarks on the Distribution of Scale-insect Parasites. By Dr. Leland O. Howard, Department of Agriculture, Washington, D. C.

3. On a collection of Cephalopoda from the 'Albatross' Expedition. By Professor William E. Hoyle, Owens College, Manchester, England.

4. On the Characters of the Brains of Nematognaths and Plectospondyls. By Dr. Benjamin T. Kingsbury, Ithaca, N. Y.

5. The Insect Fauna of Cereus giganteus. By Henry Guernsey Hubbard, Washington, D. C.

6. On the Sarcostyles of the Plumularidæ. By Professor C. C. Nutting, State University of Iowa.

7. Skeletons and Restorations of Tertiary Mammalia. By Professor Henry F. Osborn, Columbia University, New York.

C. C. Nutting,
Secretary of the Section.

University of Iowa.

SECTION G.—BOTANY.

Address of the Vice-President: Experimental Morphology. By Professor George F. Atkinson, Cornell University, Ithaca, N. Y.

1. *Trillium grandiflorum* (Michx.) Salisb.; its Variations, normal and teratological. By Professor Chas. A. Davis, Alma College, Alma, Mich.

2. Contributions on Wild and Cultivated Roses of Wisconsin and Bordering States. By J. H. Schuette, Green Bay, Wis.

3. A Discussion of the Structural Characters the Order *Pezizineæ* of Schroeter. By Dr. E. J. Durand, Cornell University, Ithaca, N. Y.

4. The Taxonomic Value of Fruit Characters in the Genus *Galium*. By K. M. Wiegand, Cornell University, Ithaca, N. Y.

5. Changes during winter in the Perithecia and Ascospores of certain *Erysipheæ*. By B. T. Galloway, Department of Agriculture, Washington, D. C.

6. The *Erysipheæ* of North America: A preliminary account of the distribution of the species. By B. T. Galloway, Department of Agriculture, Washington, D. C.

7. Some Contributions to the Life-History of *Hæmatococcus*. By Professor L. R. Jones, University of Vermont, Burlington, Vermont.

8. 'Bacteriosis' of Carnations. By Albert F. Woods, Department of Agriculture, Washington, D. C.

9. Wakker's Hyacinth *Bacterium*. By Dr. Erwin F. Smith, Department of Agriculture, Washington, D. C.

10. Notes on some new genera of Fungi. By Professor George F. Atkinson, Cornell University, Ithaca, N. Y.

11. Reproductive Organs and Embryology of *Drosera*. By C. A. Peters, Normal School, Edinboro, Penn.

12. Development of some seed coats. By Dr. J. O. Schlotterbeck, University of Michigan, Ann Arbor, Mich.

13. Morphology of the Flower of *Asclepias cornuti*. By Fanny E. Langdon. Reported by Professor V. M. Spalding, University of Michigan, Ann Arbor, Mich.

14. Comparison of the Pollen of *Pinus*, *Taxus* and *Peltandra*. By Professor George F. Atkinson, Cornell University, Ithaca, N. Y.

15. Report upon the Progress of the Botanical Survey of Nebraska. By Professor Charles E. Bessey, University of Nebraska, Lincoln, Neb.

16. Are the Trees receding from the Nebraska Plains? By Professor Charles E. Bessey, University of Nebraska, Lincoln, Neb.

17. Some Characteristics of the Foothill Vegetation of western Nebraska. By Professor Charles E. Bessey, University of Nebraska, Lincoln, Neb.

18. On the Distribution of Starch in Woody Stems. Ry Professor Bohumil Shimek, University of Iowa, Iowa City, Iowa.

19. Mechanism of Root Curvature. By Dr. J. B. Pollock. Reported by Professor V. M. Spalding, University of Michigan, Ann Arbor, Mich.

20. The Toxic Action of Phenols on Plants. By Professor R. H. True and C. G. Hunkel, University of Wisconsin, Madison, Wis.

21. Cellulose-Ferment. By Professor F. C. Newcombe, University of Michigan, Ann Arbor, Mich.

22. Is the characteristic Acridity of certain species of the Arum Family a mechanical or a physiological property or effect? Chas. Porter Hart, M.D., Wyoming, Ohio.

23. How Plants flee from their Enemies. By Professor W. J. Beal, Michigan Agricultural College, Agricultural College P. O., Mich.

24. Movements of *Phyllanthus*. By Professor D. T. McDougal, University of Minnesota, Minneapolis, Minn.

25. Stomata on the Bud-scales of *Abies pectinata*. By Dr. Alex. P. Anderson, Exp. Station, Clemson College P. O., S. Carolina.

26. Comparative Anatomy of the Normal and Diseased Organs of *Abies balsamea* (L.) Miller, affected with *Aecidium elatinum* (Alb. et Schwein.). By Dr. Alex. P. Anderson, Exp. Station, Clemson College P. O., S. Carolina.

F. C. NEWCOMBE,
Secretary of the Section.

UNIVERSITY OF MICHIGAN.

SECTION H.—ANTHROPOLOGY.

Address of the Vice-President: The Science of Humanity. By Professor W J McGee, Bureau of American Ethnology, Washington, D. C.

1. The Rite of Adoption as practiced by the Osage Tribe. By Alice C. Fletcher, Peabody Museum, Cambridge, Mass.

2. The Superstitious Beliefs and Practices of the Ancient Mexicans. By Zelia Nuttall, Peabody Museum, Cambridge, Mass.

3. Koreshanity: a Latter-day Cult. By Dr. Anita Newcomb McGee, Washington, D. C.

4. Micmac Mortuary Customs. By Dr. Stansbury Hagar, Brooklyn, N. Y.

5. Report of the Committee on the Ethnography of the White Race in America. By Dr. Daniel G. Brinton, Chairman, Media, Pa.

6. Recent Researches by George Byron Gordon, on Ulloa River, Honduras. By Professor F. W. Putnam, Peabody Museum, Cambridge, Mass.

7. Surveys of Ancient Cities in Mexico. By Professor W. H. Holmes, Field Columbian Museum, Chicago.

8. An Ancient Figure of Terra-Cotta from the Valley of Mexico. By M. H. Saville, Amer. Mus. Nat. History, New York.

9. The Serpent Symbol in Nicaragua and Yucatan. By Rev. Stephen D. Peet, Good Hope, Illinois.

10. A Case of Trephining in Northeastern

Mexico. By Dr. Carl Lumholz, Amer. Mus. Nat. History, New York.

11. Notched Human Bones from a Prehistoric Tarascan Tomb in Michoacan. By Dr. Carl Lumholz and Dr. A. Hrdlicka, New York.

12. A Cranium and Skeleton from an Ancient Burial Place in the Valley of Mexico. By Dr. A. Hrdlicka, New York.

13. An Archæologic Map of Ohio. By Warren K. Moorehead, Ohio State University, Columbus, Ohio.

14. Early Man of the Delaware Valley. By Professor F. W. Putnam, Peabody Museum, Cambridge, Mass.

15. Archæologic Researches in the Trenton Gravels. By Professor W. H. Holmes, Field Columbian Museum, Chicago.

16. Geologic Age of the Relic-bearing Deposits at Trenton. By Professor R. D. Salisbury, Chicago University, Chicago.

17. Prehistoric Implements from Charlevoix, Michigan. By H. P. Parmalee, Charlevoix, Mich.

18. Decoration of the Teeth in Ancient America. By M. H. Saville, American Museum Natural History, New York.

19. The Origin of Art as manifested in the Work of Prehistoric Man. By Dr. Thomas Wilson.

20. The Import of the Totem—A Study of the Omaha Tribe. By Alice C. Fletcher, Washington, D. C.

21. The Jessup Expedition and the Asiatic-American Problem. By Professor F. W. Putnam, Americam Museum Nat. Hist., New York.

22. Evidence of contact with Polynesia and the Asiatic Coast. By Rev. Stephen D. Peet, Good Hope, Ill.

23. The Ethnologic Arrangement of Archæologic Material. By Harlan I. Smith, American Museum Nat. Hist., New York.

24. The Tagbanna of the Philippines. By Dean C. Worcester, Ann Arbor, Mich.

25. The Mangyane of the Philippines. By Dean C. Worcester, Ann Arbor, Mich.

26. The Artificialization of Animals and Plants. By Professor O. T. Mason, National Museum, Washington, D. C.

27. Report of Committee on Anthropologic Teaching.

28. A Statistical Study of Eminent Men. By Professor J. McKeen Cattell, Columbia University, New York.

29. Mental Conditions determining the Rate of Movement. By Professor Lightner Witmer, University of Pennsylvania, Philadelphia.

30. Genesis of Implement-making. By Frank Hamilton Cushing, Bureau of American Ethnology, Washington, D. C.

SECTION I.—SOCIAL AND ECONOMIC SCIENCE.

Address of the Vice-President: Improvident Civilization. By Mr. R. T. Colburn, Elizabeth, N. J.

Beginning on Tuesday, August 10th, the following papers will be read;

1. The Civil Service Reform. By Dr. Wm. H. Hale, Brooklyn, N. Y.

2. Civic Ownership of Public Works. By Dr. Wm. H. Hale, Brooklyn, N. Y.

3. Racial Deterioration: the Increase of Suicide. By Lawrence Irwell, Buffalo, N. Y.

4. Wheat Consumption in the United States. By Henry Farquhar, Dep't of Agriculture, Washington, D. C.

5. The Municipal System of Ontario. By C. C. James, M.A., Toronto.

6. The New Canadian Tariff. By Professor James Mavor, Toronto.

7. Suggestions for an International Conference on Diversity of Languages. By R. T. Colburn, Elizabeth, N. J.

8. The 'Social Mind,' or 'Social Conscience;' its origin and persistence. By ———.

9. Tariffs and Trade. By Archibald Blue, Bureau of Mines, Toronto.

10. The Course of Ontario Agriculture durthe past ten years. By C. C. James, M.A., Toronto.

11. The U. S. idea in laying out the Public Lands and the Evils resulting therefrom. By B. W. DeCourcy, Tacoma, Wash.

12. Labor Restrictions as Potent Factors in Social Evolution. By Dr. Charles Porter Hart, Wyoming, Ohio.

13. International currency. By H. P. V. Bogne, Avon, N. Y.

ARCHIBALD BLUE,
Secretary of the Section.

BUREAU OF MINES, TORONTO.

SCIENCE

EDITORIAL COMMITTEE: S. NEWCOMB, Mathematics; R. S. WOODWARD, Mechanics; E. C. PICKERING, Astronomy; T. C. MENDENHALL, Physics; R. H. THURSTON, Engineering; IRA REMSEN, Chemistry; J. LE CONTE, Geology; W. M. DAVIS, Physiography; O. C. MARSH, Paleontology; W. K. BROOKS, C. HART MERRIAM, Zoology; S. H. SCUDDER, Entomology; N. L. BRITTON, Botany; HENRY F. OSBORN, General Biology; H. P. BOWDITCH, Physiology; J. S. BILLINGS, Hygiene; J. McKEEN CATTELL, Psychology; DANIEL G. BRINTON, J. W. POWELL, Anthropology.

FRIDAY, AUGUST 13, 1897.

New Books..260

MSS. intended for publication and books, etc., intended for review should be sent to the responsible editor, Prof. J. McKeen Cattell, Garrison-on-Hudson, N. Y.

*EDWARD DRINKER COPE, NATURALIST—A CHAPTER IN THE HISTORY OF SCIENCE.**

I.

Bitter constraint, and sad occasion dear
Compels me to disturb your season due;
For Lycidas is dead, dead ere his time
Our Lycidas, and hath not left his peer.

ON the morning of the 13th of April, in a car on my way from a funeral in New York to Washington, a newspaper notice of the death, the day before, of my old friend, E. D. Cope, caught my eye. Shocked by the intelligence, I dropped the paper, and memory recalled various incidents of our long acquaintance.

The threnody of Milton* in commemoration of his friend Edward King also rose to recollection, and the lines just quoted seemed to me to be peculiarly fitted for the great man just dead. He was, indeed, no longer young and had attained his prime,† but he had planned work for many years to come and had well advanced in the execution of some of it. He had truly died before his time and had left no peer; the greatest of the long line of American naturalists was prematurely snatched from science and from friends.

My acquaintance with Cope began in 1859. While looking through the part of the Proceedings of the Academy of Natural Sciences of Philadelphia for the month of April, in which my first paper published by the Academy had appeared, I found one by E. D. Cope 'On the primary divisions of the Salamandridæ.' It seems that the papers by Cope and myself had been passed on by the Committee on Publications on the very same day (April 26th) and appeared in print in juxtaposition. I had not previously

heard of the new devotee of science and read his article with as much interest as my own. A well-equipped man had evidently come upon the field and this was the first of the numerous articles that were destined to appear in an uninterrupted flow for nearly four decades. A few months afterwards I met the author in Philadelphia at the Academy. A young man, nineteen years old, about 5 feet 9 or 10 inches high, with head carried somewhat backwards and of rather robust frame, stood before me; he had an alert, energetic manner, a pronounced, positive voice, and appeared to be well able to take his part in any trouble. His knowledge was by no means confined to herpetology, but covered a wide range of science, and his preliminary education had been good. We afterwards met from time to time in Philadelphia and Washington and found we had many sympathies in common and some differences.

In one of our first interviews we had quite an argument on the nature of the family group in zoology, resulting from criticisms I made on the extended scope he had given to that category in the classification of the Salamanders. Another controversy, I remember, had reference to the vertebral theory of the skull. In an article on the venomous serpents, published in the Proceedings of the Academy for 1859, he had defined the group in terms involving the adoption of that theory, and I ventured to dissent from its reality. I had myself been much impressed with it in former days and when 16 years old had copied in colors an illustration of Owen's so-called archetype reproduced in Carpenter's Physiology. Subsequently, however, the fact that there was only an approximation to the realization of it in the most specialized of fishes and not at all among the lower or higher vertebrates, with other considerations, turned me from it, and I gave my reasons for dissent to Cope. Ultimately he admitted the force of the argument and also abandoned the theory at one time so popular in England and America.

Our acquaintance, thus begun in 1859, continued uninterruptedly till death divided us. We rarely met, indeed, that we did not express difference of opinion respecting some subject, but the difference was never of a serious nature and generally little more than sufficient to enliven intercourse.

II.

The future naturalist was born in Philadelphia on the 28th of July, 1840, and the name Edward Drinker was given to him. He was the descendant of a prosperous line long established in Pennsylvania. His father, Alfred, was a man of cultivated literary taste and did much to train his son's mind in early youth. He had retired from active business and lived in luxurious ease in Germantown, a suburb of Philadelphia. There he had formed an arboretum containing most of the American trees which would thrive in the climate of that region. Amidst such surroundings the youthful Cope grew up.

An active and intelligent interest in Nature became manifest at a very early age. When only about seven years old, during a sea voyage to Boston with his father, the boy is said to have kept a journal which he filled with drawings of 'jelly fish, grampuses and other natural objects seen by the way.' When eight and a half years old he made his first visit to the Museum of the Academy of Natural Sciences of his native city; this visit was on the "21st day of the 10th Month, 1848," as entered in his journal. He brought away careful drawings, measurements and descriptions of several larger birds, as well as of the skeleton of an Ichthyosaurus. His drawing of the fossil reptile bears the explanatory legend in Quaker style: "two of the sclerotic plates look at the eye—thee will see these in it."

At the age of ten he was taken upon a voyage to the West Indies.* What were the impressions he derived from that voyage we have not been told. But what has been communicated amply justified Professor Osborn in his declaration that "the principal impression he gave in boyhood was of incessant activity in mind and body, reaching in every direction for knowledge, and of great independence in character and action." His school education was mostly carried on in the Westtown Academy, a Quaker institution about 23 miles west of Philadelphia. One of his instructers was Dr. Joseph Thomas, a well known literary worker of Philadelphia and future author of a 'Universal Pronouncing Dictionary of Biography and Mythology' (1870), and said to be an 'excellent linguist.' Under his guidance Cope obtained a passing knowledge of Latin and Greek. He appeared to have had no instruction in any biological science and had no regular collegiate training. He did, however, enjoy the advantage of "a year's study (1858–9) of anatomy and clinical instruction at the University of Pennsylvania," in which the illustrious Leidy was professor of anatomy. But, in the words of his literary executor (Professor H. F. Osborn), "it is evident that he owed far more to paternal guidance in the direct study of nature and to his own impulses as a young investigator than to the five or six years of formal education which he received at school. He was especially fond of map drawing and of geographical studies."

While a school boy he relieved his studies of the classics and the regular course in which boys of his age were drilled by excursions into the fields and woods. Reptile life especially interested him, and he sought salamanders, snakes and tortoises under rocks, stones, fallen trees and layers of leaves, as well as in the ponds and streams of his vicinage. The trophies of his excursions were identified from descriptions in the works in which they were treated, as well as by comparison with identified specimens in the museum of the Academy. He early and almost without guidance learned to use the library and collection of the Academy, although he did not become a member until he came of age in 1861.

*Osborn in Science, n. s., V., 706.

Cope's first contribution to the Proceedings of the Academy appeared in the part covering April and was 'On the Primary Divisions of the Salamandridæ, with descriptions of the New Species.'* In this maiden paper he instituted important modifications of the systems previously adopted in the United States. He soon afterwards catalogued the serpents preserved in the museum of the Academy of Natural Sciences and likewise improved upon the systems previously in vogue. He continued with various papers, describing new species and giving synopses or brief monographs of sundry genera of lizards and anurous amphibians.

For five years his publication was confined almost exclusively to the reptiles and amphibians. (The continuity was only interrupted once in 1862, when he described a new shrew caught by himself in New Hampshire.) Not until 1864 did he begin to extend his field. In that year he described various fishes and a supposed new whale, and gave his first contribution to paleontology in the description of the stegosaurian amphibian called *Amphibamus grandiceps*. But although his attention had become thus divided, he never lost his interest in herpetology and continued to the end of his life to devote much attention to that department. His studies extended to every branch of the subject, covering not only specific details and general taxonomy, but also the consideration of anatomical details, the modifications of different organs, geographical distribution,

*Proc. Acad. Nat. Sci. Phila., 1859, pp. 122–128.

chronological sequence, genetic relations and physiological consequences. So numerous were his memoirs, so entirely did he cover the field of herpetology, and so marked an impression did he make on the science, that he was well entitled to apply to himself the boast of the Vergilian hero, '*Pars magna fui.*'

In his earliest essays he manifested the independence and critical spirit which were so characteristic of him later. One knowing all the circumstances of the case may be amused in coming across a passage expressed in the tones of a veteran published by him when 20 years old: "In proposing the name Zaocys * * * we are giving expression to an opinion *long held by us* as to the unnatural association of species in the so-called genus *Coryphodon* * * *. In it we find cylindrical terrestrial species united with compressed subarboricole species, upon a peculiarity whose value as an index of nature appears to us entirely imaginary. The very nature of the *coryphodontian* type of dentition, as distinguished from the *isodontian* and *syncranterian*, would lead us to infer its inconstancy;" and so on.* Bold as was the criticism of such herpetologists as Duméril, Bibron and Günther, it was justified by the facts, and the young author's conclusions have received the endorsement of the best succeeding herpetologists, including even the latest author criticised.

In 1863 he paid a visit to Europe, partly for the benefit of his health which had suffered from overwork, and partly for the purpose of seeing the great museums of England, France, Holland, Austria and Prussia. Notwithstanding his ailments, he made good use of his time abroad and systematically examined the collections of reptiles in the chief centers of science. He did not even restrict his studies to herpetology, but extended them to various other subjects.

*Proc. Acad. Nat. Sci., Phila., 1860, p. 563.

On his return from Europe, in 1864, he was appointed professor of natural science in Haverford College, an institution chiefly supported by Quakers, but retained the position only three years. During this time, in 1865, he married Miss Annie, daughter of Mr. Andrew Pim, of Chester county, Pa.

In and after 1864, too, he enlarged the range of his studies and publications and also extended them to ichthyology, mammalogy and paleontology. He had always been interested in the philosophical aspects of science and early adopted the conception of descent with modifications to account for the variations of animals and the differentiation into species and higher groups, and in 1869 began to give expression to his peculiar views.

On the death of his father he became heir to a considerable fortune. Part of this was invested in mines which for a short time gave promise of good returns, but, it is said, the majority of the stock was held by others, and owing to the incapacity of superintendents and the operations of the controlling stockholders he lost his interests. While in the enjoyment of his fortune he spent large amounts in collections and personally conducted or sent out expeditions to various places. One of the most important was sent to South America. He filled a large house from cellar to topmost story with his collections and resided in an adjoining one.

In 1871 he conducted an expedition to Kansas and especially investigated the Cretaceous beds of that State and collected their fossils. In 1872 and 1873 he became connected with the U. S. Geological Survey and for the fossils visited Wyoming in the former year and Colorado in the latter. In 1874 he joined the survey under the command of Lieut. Wheeler, of the Engineers, and explored New Mexico.

The collections made during these expeditions were large and the unwearied in-

dustry and energy, as well as cares, of Cope were rewarded with many well-preserved fossils. These were described in many communications to the Academy of Natural Sciences and the American Philosophical Society, and later in large volumes published by the general government as reports of the respective surveys with which he was connected.

The various investigations thus opened were continued through the succeeding years. His collections continued to grow in spite of reduced means. He refused even to sell portions for which he was offered liberal sums and, at the cost of personal discomfort, held on to them and made his home, for much of the time, in the midst of them, having sold his residential house but kept his museum.

In 1878 he purchased the rights of the proprietors of the *American Naturalist* and removed it to Philadelphia. Professor Packard, one of the original proprietors, cooperated with him in the editing of it for some years, and he was also assisted by various eminent specialists. In this journal numerous articles of all kinds, including reviews and editorial comments, were published by him. His last words appeared in numbers issued after his death, the leading article in the number for June having been written shortly before his death ; it treats of the remarkable mammals of South America, known as Toxodontia.

In 1886 he received an appointment to a chair in the University of Pennsylvania and became professor of geology and paleontology. Such a man naturally awakened the interest of apt pupils, and he was a facile and entertaining lecturer. From the stores of a rich memory he could improvise a discourse on almost any topic within the range of his varied studies. His views were so much in advance of those in any text-book that for his own convenience, no less than for the benefit of his pupils, he felt compelled to prepare a 'Syllabus of lectures on geology and paleontology,' but only 'Part III., Paleontology of the Vertebrata,' was published. It appeared in 1891 and is still a valuable epitome of the classification of the vertebrates, recent as well as fossil, giving in dichotomous tables the essential characters of all the groups above families and also the names of all the families. His own industry and investigations did much to render this antiquated in even six years and a new edition or work became necessary. "Upon the Tuesday preceding his death he sent to the press an elaborate outline of his University lectures containing his latest ideas of the classification of the Vertebrata."*

The enormous mass of publications constantly flowing from his own pen might lead one unacquainted with the author to suppose that he was probably a recluse, but there were few men of his intellectuality who were less disposed to seclude themselves. He enjoyed and gave enjoyment to intellectual company and was a brilliant conversationalist. He was especially fond of academical meetings and was an unusually frequent attendant at the meetings of the American Association as well as of the National Academy of Sciences. His election to the Presidency of the American Association was highly esteemed by him and doubtless his address would have been a notable one.

In February (1897) Cope's health became seriously affected by nephritic disorder, which, it is said, 'might possibly have been remedied by a surgical operation,' but this he would not submit to. Notwithstanding failing health, he continued active almost to the last. Finally the insidious disease invaded his entire system and he died on the 12th of April, in the room he had long used as a study, surrounded by the objects of his life-long attentions.

* Osborn in SCIENCE, May 7, p. 705.

Such were the chief episodes of Cope's individual life; the facts known are few and the record belongs rather to his family than to us. But Cope's real life was in his work and to the consideration of that work we may now proceed. Let us adopt the order in which he took up the subjects of his investigations and successively look into his contributions to herpetology (III), ichthyology (IV), mammalogy (V) and paleontology (VI); we may then examine his philosophical views and especially those relating to evolution (VII); finally we may attempt to forecast the position he is destined to enjoy in the history of science (VIII). To know him as he was we must recognize his weakness as well as his strength. He himself has wished this and has asked in the spirit of the Moor:

> Speak of me as I am; nothing extenuate,
> Nor set down aught in malice.

III.

The extent of Cope's contributions to herpetology have been referred to. Herpetology was his first love and continued to be the favorite branch of science to his life's end. His impress on it was, in some respects at least, greater than on any other of the sciences he cultivated, and doubtless the systems he introduced, with some modifications, will be the most lasting. He found herpetology an art; he left it a science; he found it a device mainly for the naming of specimens; he left it the expression of the coordination of all structural features. The reformations he effected in the classification of the anurous amphibians and the saurian reptiles were especially notable.

The anurans had been chiefly differentiated in groups on account of the most superficial characters. Such were the modes of fixation of the tongue or its absence, the development of disk-like expansions of the tips of the toes, or simply attenuated toes, and the presence or absence of teeth in a jaw. Cope proceeded to investigate the group in an anatomical manner and reached entirely new conclusions. He found that important differences existed in the structure of the sternum, and especially in the connection of the lateral halves. In the common toads and tree toads of Europe and North America the so-called clavicle and coracoid of each side are 'connected by a longitudinal arched cartilage which overlaps that of the opposite side,' while in the common frogs the clavicles and coracoids of both sides are connected by a single median cartilage. The former type is now known as the arciferous and the latter as the firmisternal. Although Cope was the first to appreciate the significance of those characters, he did not at once fully realize their morphological value, the name Arcifera having been originally applied by him only to types of that group having teeth. Ultimately he did so, and his views have stood the test of time and the latest critical investigations. He also found that the characters so revealed served to fix the places in the system of the groups in question. In their early stages the Firmisternials (or frogs and their relations) have the shoulder-girdle movable, and thus resemble the Arcifers (toads, etc.), which have the opposite halves movable during their whole lifetime; thus it became evident that the latter are the lowest or most generalized forms, and the former more advanced and higher in the system. The development of teeth, which had been supposed by the earlier systematists to be of paramount value, and which Cope, following in their footsteps, had also originally unduly valued, has been found to be of quite subordinate importance.

The lizards were also in former times distributed into families and other groups on account of variations in superficial or external characters, such as the form of the tongue, the arrangement of the scales and the development of legs and feet. Cope

dissected examples of all the types he could obtain and found that such superficial characters were often misleading, and he proceeded to arrange them with reference to the preponderance of all characters. The structure of the cranium especially was analyzed, and the variations and concordances in the development of various bones were tabulated. These characters were supplemented by others derived from the vertebræ, the shoulder girdle, the teeth, the tongue and the pholidosis. Familiarity with his subject enabled him almost instinctively to assess the relative values of the different characters, and he obtained fitting equations which resulted in a system which has received the approbation of the most competent judges to the present time.

The extent of Cope's influence on herpetology may be to some extent inferred from the catalogues of the richest collection of reptiles and amphibians in existence—the British Museum's. Descriptive catalogues of both the Anurans and Saurians have been published at different times. In the early catalogues are adopted the views current at the dates of publication—1845 for the lizards; 1858 for the batrachians. New editions were published many years later and the systems of Cope were adopted with slight modifications. In his catalogue of the *Batrachia salientia* Mr. Boulenger, the author, remarked that it appeared "undeniable that the principles of classification laid down by Mr. Cope are more in accordance with the natural affinities of the genera of tailless Batrachians than those employed by other authors; this is amply proved by all we know of their geographical distribution, development and physiology."

In an article* published in advance of his catalogue of the lizards, Boulenger states that the old classifications are, 'on the whole, as unnatural as can be' and that, "like Cope, whose lizard families I regard as the most natural hitherto proposed, I shall lay greater stress on osteological characters and on the structure of the tongue."

*Synopsis of the families of existing Lacertilia. Ann. and Mag. Nat. Hist. (5), XIV., 117.

It was a long time, however, before Cope's views became popular. Even anatomists of repute refused to follow him. One* of them, for example, admitted that "skeletal characters are, indeed, most valuable ones in leading us to detect the deepest and truest affinities of vertebrate animals, but [he urged] these affinities once found, it is very desirable that zoological classification should not, if it can possibly be avoided, *repose* upon them only, but rather on more external and more readily ascertainable characters." He, therefore, ventured 'to propose a classification derived from that of Dr. Günther.'

Cope replied† by a fierce review of the work of Dr. Günther, and concluded with the utterance that such views 'will only interfere with the progress of knowledge if sincerely held and believed.'

But such views were evidently sincerely believed and they did retard the progress of science. An eminent Russian herpetologist objected to the use of anatomical characters. He especially protested against those employed by Boulenger after Cope to the grouping of the lizards, and Mr. Boulenger considered it incumbent on him to defend the practice of using such characters; ‡ he aptly replied that the use of 'purely external characters * * * does not meet the requirements of modern science,' and that classifications are not made simply 'for the convenience of beginners.'

At last, however, the principles of classification adopted by Cope have become gen-

*Mivart in Proc. Zool, Soc., London, 1869, p. 281.

†Cope in Am. Journ. Sci. (3), I., p. 203.

‡Boulenger in Ann. and Mag. Nat. Hist. (5), XIX. 385.

erally accepted, and doubtless this was in no small degree hastened by their application to all the amphibians and reptiles by Boulenger.

Cope's attention to the extinct reptiles was excited by the examination and consideration of a Carboniferous lizard-like amphibian which he was requested in 1865 to report upon. It was a new species which he named *Amphibamus grandiceps* and considered to be the type of a new order to which the name Xenorachia was applied, but which he subsequently referred to the new comprehensive order Stegocephali.

He sought for specimens of the extinct species with as much enthusiasm as he had for the recent. Extinct and living he considered together and light was mutually reflected from the two to guide him in the perfection of the entire system. In 1869 he gave expression to the results of his studies in a well illustrated 'Synopsis of the Extinct Batrachia, Reptilia and Aves of North America.' This was supplemented in 1874 by addenda and a 'Catalogue of the air-breathing Vertebrata from the coal measures of Ohio.'

A rich field was opened to him in 1877, when he received the first instalment of reptilian remains from Texas, which were at first considered to be of Triassic age, but subsequently determined to be Permian. Successive instalments of amphibian as well as reptilian skeletons enriched his collection, and his investigations revealed a new and wonderful fauna rich in species and often differing widely from any previously known. These were described in many articles. The results for the amphibians were summarized in 1884 in a memoir on the 'Batrachia of the Permian period of North America.'

The Permian amphibians were found to vary much in the composition of their backbones. Instead of having single centra arranged in a continuous row as in existing Vertebrates, they had distinct bones on which were devolved portions of the functions fulfilled by the centra of higher Vertebrates. Some had 'the vertebral bodies represented by three segments each, a basal intercentrum and two lateral pleurocentra;' these were named 'Ganocephali' and 'Rhachitomi.' Some "differ remarkably from all other Vertebrata in having between the centra another set of vertebral bodies, so that each arch has two corresponding bodies;" these were called 'Embolomeri.'

In tracing the development of these bones, Cope came to the conclusion that they were only partially represented in higher or more specialized types; they did not become consolidated, but one or the other became reduced and finally lost or at least greatly atrophied. In the living amphibians the vertebral centra are homologous only with the intercentra, while, on the contrary, the centra of the reptiles, birds and mammals are represented by the pleurocentra of the Rhachitomes.

The studies of Cope on those classes which had earliest attracted his attention were more nearly completed than for any others. Many years ago he had contemplated the publication of monographs of the amphibians and reptiles of North America and happily he had at last finished his work.

In 1889 his monograph of the 'Batrachia of North America' was given to the world as a Bulletin of the United States National Museum (No. 34). It forms a goodly volume of 525 pages illustrated by 86* plates and 120 figures inserted in the text. No large country has a more elaborate and scientific exposition of the class than is given in this volume. A synopsis is furnished of all the families and genera wherever found, and detailed descriptions are supplied for all the groups and species

* The last plate is numbered 86, but five were cancelled, 80, 81, 82, 84 and 85.

represented in the zoological realm of North America, 31 genera and 107 species are recognized, and of these Cope had first made known about a quarter, 7 of the genera and 27 of the species having been described by himself. Shortly before his death, and during his last visit to Washington he delivered to the National Museum the report on all the reptiles of North America which he had been long preparing. This was prepared on the model of his 'Batrachia of North America,' but will, of course, be a much larger work, inasmuch as there are nearly three times as many reptiles as Batrachians.* His last elaborate memoirs dealt with special anatomical features of the serpents and lizards, which he examined with the view of perfecting the system of those groups.

IV.

In 1864 he became especially interested in the fresh-water fishes of the United States, and then as well as in succeeding years published enumerations and descriptions of many species. His first papers in 1864 and 1865 were 'On a blind Silurid from Pennsylvania' and a 'Partial catalogue of the cold-blooded Vertebrata of Michigan;' in 1868 he published 'On the distribution of fresh-water fishes in the Allegheny region of southwestern Virginia,' and in 1869 appeared a 'Synopsis of the Cyprinidæ of Pennsylvania.' In addition to these, various minor papers were published and in some of them marine forms were considered.

When in Europe Cope had purchased a large collection of skeletons of fishes from all parts of the world prepared by Professor Joseph Hyrtl, of Vienna, one of the most skillful practical anatomists of the day. He had a number of other skeletons made to represent missing types. With these as a basis he proceeded to recast the classification of fishes. The first contribution to the subject was embodied in an introductory chapter of his 'Contribution to the Ichthyology of the Lesser Antilles,' published early in 1871.

The same chapter, with the same title, 'Observations on the Systematic Relations of Fishes,' but with some modifications and additions, was later published in the Proceedings of the American Association for the Advancement of Science for 1871. This was a notable paper and replete with original observations of value. It was not, however, up to the standard of his work on amphibians and reptiles. The subject, indeed, was too vast and only a superficial examination was made of special parts. It was not a classification based on the examination of the entire structure, but rather an exposition of the development of a few particular characters, which more experience subsequently convinced him were of less value than he had supposed. Nevertheless, in some respects the proposed classification was much in advance of those previously adopted, and useful hints were given for the further improvement of the system.

Later Cope followed up this attempt at the reformation of the ichthyological system with several others especially treating of extinct types. One of them, 'On the classification of the extinct fishes of the lower types,' was published in the Proceedings of the American Association for 1877. The results of his studies were summarized, in 1889, in 'A synopsis of the families of Vertebrata,' and two years afterwards (1891) with modifications, in an article 'On the non-actinopterygian Teleostomi.' These results were very valuable and attention was for the first time directed to the importance and morphological significance of the skeletal fin structures of the ancient fishes long confounded under the name of Gan-

* Cope's monograph of the reptiles will not include the tortoises, those having been left to Dr. G. Baur to monograph.

oids. Instead of this single order (or subclass) of the old systematists, he named four superorders of the Teleostomi or true fishes,' and recognized seven orders, including the old ganoids after eliminating the Lepidosteids and Amiids, which were referred to the Actinopterygians. Only two of the seven orders are represented by existing forms—one (*Cladistia*) by the bichirs of Africa and the other (*Chondrostei*) by the sturgeons.

His work on the extinct fishes was incomparably better than any that had been done before in the United States. He far surpassed all his predecessors, not only by his knowledge of morphological details manifest in the extinct as well as living forms, but by his keen philosophical instinct and taxonomic tact. But this philosophical instinct was sometimes at fault, and occasionally he indulged in the wildest speculations, for which he has, not unjustly, been taken to task. But even his blunders were the result of the facility of his mind in seizing and adapting the latest utterances of science. One notorious case may be given. The great Russian embryologist Kowalevsky published a memoir sustaining the thesis that the Tunicates were members of the vertebrate phylum and that the larval stage of most of the species had the homological equivalent of the backbone of the true vertebrates. Cope foresaw the morphological consequences of this view and sought the vertebrates nearest the Tunicates. He settled upon some strange forms of the Silurian and Devonian times known as Pteraspids and Cephalaspids. They were the earliest known of vertebrates and therefore likely to be the most primitive in structure. Most of them had a shell-like encasement, composed of bone-like plates. He happened to find illustrations of the living *Chelyosoma*, a true Tunicate having a system of plate-like indurations of the integument, somewhat similar in appearance to those of some of the ancient fishes. It was assumed that this mere superficial similarity indicated genetic relationship. To those acquainted with the structure of *Chelyosoma* this approximation seemed strange indeed; its anatomy was known and the form is simply a well marked relation of the typical ascidiids, but highly specialized by the development of integumentary plate-like horny indurations. Histologically and otherwise they were very different from the plates of the extinct armored vertebrates. Cope's guess was simply the result of the tendency to jump at conclusions which he was constantly obliged to curb, and unfortunately he rushed into print before he had time to think. He soon reconsidered the case with calmer mind, and abandoned his hypothesis. Few men were ever more willing to reconsider evidence and retrace false steps than he.

In spite of errors of detail and somewhat hasty generalization the ichthyological labors of Cope were unusually valuable contributions to science, and the progress of ichthyology has been much accelerated, not only by these labors, but by the investigations they challenged.

V.

Cope's attention was early drawn to the mammals. His first published article (1863) was a description of a supposed new Shrew found in New Hampshire, and in 1865 he described various cetaceans. In 1868 he began the collection and investigation of the fossil mammals of the western territory, and thenceforward devoted the larger share of his attention to the description and restoration of the numerous new species which he from time to time brought to light. The previous investigators of the extinct mammals of America had almost exclusively confined themselves to descriptions and illustrations of the crania and dentition, but a new era was intro-

duced when Marsh and Cope sent out exploring expeditions or themselves collected. No parts of skeleton were neglected; all were collected. Gradually the numerous bones from different parts of the skeleton were identified, and finally many of the beasts of old were resurrected into skeletons almost as complete as those just divested of muscles.

The discoveries resulting from such thorough work quite modified or even overturned old conceptions. It became evident that there was a great contrast between the development of the mammals and that of invertebrates, and even, though in a less degree, of fishes. It appeared that there was a much more rapid process of evolution for the mammals than for the lower classes. All the mammals of the oldest of the Tertiary periods were strange and very unlike those of recent times, and no descendants of even the same families lived to be the contemporaries of civilized man. The views of the founder of vertebrate paleontology were also to a considerable extent subverted. Cuvier taught that there was always a coordination between the various systems of the animal frame and that from the remains or impress of one part the approximate structure of the other parts could be inferred. He even pushed this doctrine to such an extreme that he overlooked some obvious counter-facts. One such case is so remarkable because it orginated with Cuvier and was endorsed by Huxley* that it is worthy of mention here, and Huxley's introduction to it and translation of it may be given. Huxley himself protests against the too literal application of Cuvier's law and recalls Cuvier's own reserve:

"Cuvier, the more servile of whose imitators are fond of citing his mistaken doctrines as to the nature of the methods of paleontology against the conclusions of logic and of common sense, has put this so strongly that I cannot refrain from quoting his words.*

"But I doubt if any one would have divined, if untaught by observation, that all ruminants have the foot cleft, and that they alone have it. I doubt if any one would have divined that there are frontal horns only in this class; that those among them which have sharp canines for the most part lack horns.

"However, since these relations are constant, they must have some sufficient cause; but since we are ignorant of it, we must make good the defect of the theory by means of observation. It enables us to establish empirical laws, which become almost as certain as rational laws, when they rest on sufficiently repeated observations; so that now, whoso sees merely the print of a cleft foot may conclude that the animal which left this impression ruminated, and this conclusion is as certain as any other in physics or morals. This footprint alone, then, yields to him who observes it, the form of the teeth, the form of the jaws, the form of the vertebræ, the form of all the bones of the legs, of the thighs, of the shoulders, and of the pelvis of the animal which has passed by. It is a surer mark than all those of Zadig."

The first perusal of these remarks would occasion surprise to some and immediately induce a second, more careful reading to ascertain whether they had not been misunderstood. Some men, with much less knowledge than either Cuvier or Huxley, may at once recall living exceptions to the positive statements as to the coordination of the 'foot cleft' with the other characters specified. One of the most common of domesticated animals—the hog—would come up before the 'mind's eye,' if not the actual eye at the moment, to refute any such correlation as was claimed. Nevertheless, notwithstanding the fierce controversial literature centered on Huxley, no allusion appears to have been made to the lapsus. Yet every one will admit that the hog has the 'foot cleft' as much as any ruminant, but the 'form of the teeth' and the form of some vertebræ are quite different from those of the ruminants, and of course the multiple stomach and adaptation

*Huxley, 'Introduction to the Classification of Animals,' 1869, in first chapter 'On Classification in General.'

*Ossemens fossiles, ed, 4^{me}, tome, 1^{r}, p. 184.

for rumination do not exist in the hog. That any one mammalogist should make such a slip is not very surprising, but that a second equally learned should follow in his steps is a singular psychological curiosity.

I need scarcely add that the law of correlation applied by Cuvier to the structures of ruminants entirely fails in the case of many extinct mammals discovered since Cuvier's days. Zadig would have been completely nonplussed if he could have seen the imprint of an Agriochœrid, a Unitatherid or a Menodontid.

I have given this quotation for two reasons: first, to indicate how the increase of our knowledge has revolutionized old conceptions; and second, to show how even the ablest of men may stumble.

Cope has been much criticised for the mistakes and false generalizations he made. Unquestionably he did make many. But error seems to be inseparable from investigation, and if he made more than the other great masters he covered more ground and did more work. He was also, it must be admitted, more hasty than some others in that he availed himself of the more frequent means of publication he enjoyed.

The great merit of Cope's work on mammals is that he always considered the old and new—the extinct and recent—forms together. He refused to be bound by consistency or by precedent, either set by himself or others. Fresh discoveries opened new vistas to him, and he modified his views from time to time and as often as he received new evidence.

He introduced many new families in the system and sought to improve the system by the comparison of all the elements of the skeleton. He came to the conclusion that the affinities of the ungulate quadrupeds was best expressed by the manner of articulation of the bones of the carpus and tarsus; he associated those having the 'carpal and usually tarsal bones in linear series' in a great order which he called Taxeopoda, and contrasted them with the Proboscidea and typical Ungulata, which he named anew Diplarthra. In the Taxeopoda he gathered many extinct families and associated with them forms of the existing fauna known as the Hyracoidea, Daubentonioidea, Quadrumana and Anthropomorpha. I cannot altogether assent to this collocation inasmuch as I think the common characteristics of the three groups last mentioned—especially the structure of the brain and the development of the posterior cornua of the ventricles as well as calcarine sulci—justify the old order Primates. Nevertheless an important character was first appreciated in the composition of the podial bones, and fresh insight was obtained into the relations of ancient types.

I can only name a few more of Cope's discoveries in this connection. One was the generalization of 'trituberculy,' or the original development of three tubercles to molar teeth, and that subsequent modifications of the corresponding teeth were based on this original plan. Another was the remarkable *Phenacodus* of the Eocene, which was considered to be nearly in the line of descent for the ungulates as well as the series culminating in man and which led him to the conception of the taxeopodous group.

The past history and genealogy of the Camels and their relations were likewise elucidated. In the present epoch only two nearly related types exist separated by half the globe—the true camels of central and northern Asia and the llamas of the Peruvian Andes. Cope revealed numerous species from various Tertiary beds and showed that the type was originally richly developed in America.

VI.

Paleontology from more than one point of view may be divided into Invertebrate and

Vertebrate. The subjects of the former are generally to be found in an approximately complete condition so far as the exterior is concerned, and early attracted the attention of investigators, often little familiar with recent zoology, and received names. The subjects of the latter—especially the higher types, as mammals, birds and reptiles—are rarely found, except in a fragmentary condition. Special knowledge of osteology, even to its minutest details, is requisite to successfully deal with such remains. Consequently the fossil vertebrates of the United States were neglected and left to the few who had cultivated the requisite knowledge to deal with them.

Another reason existed for the tardy attention to Vertebrate paleontology, which continued till nearly the last quarter of our present century in the United States. No deposits containing many fossil vertebrate remains had become known in the East. Zoologists interested in the past and in the genealogy of existing forms lamented the poverty of the United States, which contrasted with the richness of some parts of Europe. It was even thought that there was no hope of finding here such trophies of the past as the beds of the Paris Basin or those of Grecian Pikermi had yielded to European paleontologists. But all this was to be changed. Rumor had long before hinted that numerous skeletal remains could be found in certain parts of the wild West, but the information was very vague. Enough was known, however, to induce Professor Marsh to visit certain deposits he had heard of. In 1870 he explored an Eocene lake-basin in Wyoming, drained by the Green river, the main tributary of the Colorado, and therein found numerous bones belonging to almost all parts of the skeleton, of some remarkable gigantic mammals which he called Dinocerata. The results of this exploration interested Cope in the highest degree. He visited the same region in 1872, and thenceforth his attention to the Vertebrate paleontology of the Western States and Territories was never interrupted. An intense rivalry arose between Professor Marsh and himself which in time, it must be confessed, became very bitter. Nevertheless, as in most quarrels respecting facts, investigations were provoked by mutual recriminations which resulted in a more speedy accumulation of data and a more critical examination of those data than would have been likely under less perturbed conditions. Most of those data relate to morphological and anatomical considerations, and therefore belong rather to mammalogy and herpetology than to geology.

The relations of the ancient forms to each other in point of time; to those of other lands; and to those whose remains were embedded in other rocks, had necessarily to be investigated. The earliest conclusions of Cope were brought together and published in 1879 in a memoir on 'The Relations of the Horizons of Extinct Vertebrata of Europe and North America.'* He attempted therein to synchronize, or, rather, homotaxially correlate the various ancient fauna of North America and 'West Europe' from the 'Primordial' to the 'Pliocene.' Naturally the greater part of the memoir was devoted to the consideration of the Tertiary divisions; of these he admitted for the American form six primary divisions, and four of these were dichotomously subdivided for the time. Of the primary divisions three were referred to the Eocene, one (White River) to the Oligocene, one (Loup Fork) to the Miocene, and one to the Pliocene. The exposition thus made represents views not very different from those now held, although, of course, modifications in details have since been necessary.

The evolution of the various animal, and especially mammalian types, was also con-

*Bull. U. S. Survey Terr., V., 33-54.

tinually the subject of Cope's researches, and he attempted to trace the passage from those of the most ancient periods to those of later ones.

VII.

Cope was not satisfied with the study of morphological details or simple taxonomy. He aspired to know how animals came into existence; why they varied as they did, and what laws determined their being. His was an eminently philosophical mind, but at the same time with a decided tendency to metaphysical speculation. In one of his earliest papers he manifested this tendency and it persisted through life. It is with much hesitation that I venture to give an exposition of his most salient views, for I must confess I do not altogether like his philosophy and am able to subscribe to it only in part. I cannot but wish that one of his numerous disciples could have been chosen for this task. But I cannot pass it by, for it is the most characteristic feature of Cope's work and the one he most esteemed.

Cope began his public scientific career, it will be remembered, in the same year in which Darwin's long studies had fructified into his 'Origin of Species.'

As was quite natural with his keen instincts, Cope early adopted the doctrine of transmutation of species and recognized the truth that all the animals of the present epoch are descendants from those of past times with modifications which separate them as species, and eventually as representatives of genera, of families and orders differing from the earlier ones as we retrace the steps of Time farther and farther back. He was not, however, satisfied with Darwin's theory, and denied that natural selection was a sufficient factor for differentiation. He would not admit that animals were passive subjects and that the slight variations which were manifest in the progeny of species were sufficient to enable nature to select from and to fit for future conditions. He contended that the volition and endeavors of an animal had much to do with future progeny as well as its own brief life. In short, he claimed that characters acquired by animals through their own efforts or forced on them by various external agencies or accidents might be transmitted to their offspring. He further, first in a in a chapter in his 'Synopsis of the Cyprinidæ of Pennsylvania' outlined, and later, × in 'The Origin of Genera,' ~~he~~ elaborated, a peculiar theory characterized mainly by what he called (with Professor Hyatt) 'the law of *acceleration* and *retardation*' in development. Darwin complained that he could never understand this law, and Cope complained that Darwin had not stated his views correctly in an attempted abstract. I therefore give Cope's views, restated in his own language, summarizing them years afterwards. "The following doctrines," he he says, "were taught:"

"First, that the development of new characters has been accomplished by an *acceleration* or *retardation* in the growth of the parts changed. This was demonstrated by reference to a class of facts, some of which were new, which gave ground for the establishment of the new doctrine.

Second, that of *exact parallelism* between the adult of one individual or set of individuals and a transitional stage of one or more other individuals. This doctrine is distinct from that of inexact parallelism which had already been stated by von Baer. And that this law expresses the origin of genera and higher groups, because,

Third, they can only be distinguished *by single characters* when all their representatives come to be known.

Fourth, that genera and various other groups have descended, not from a single generalized genus, etc., of the same group, but from corresponding genera of one or more other groups. This was called the doctrine of *homologous groups*.

Fifth, the doctrine that these homologous groups belong to different geological periods, and,

Sixth, to different geographical areas, which, therefore, in some instances, are,

Seventh, related to each other in a successional way like the epochs of geological time.

× Tr. A.P.S. 13, 399, 186

"Of these doctrines it may be observed that the first and second are now the common property of evolutionists, and are recognized everywhere as matter of fact. The names which I selected to express them have, however, only come into partial use. The author believes that, although the doctrine was vaguely shadowed out in the minds of students prior to the publication of this essay, it had not previously been clearly expressed, nor been reduced to a demonstration. Of the truth of the doctrine the author is more than ever convinced, and he believes that paleontological discovery has demonstrated it in many instances, and that other demonstrations will follow. The fourth proposition (that of homologous groups) is now held as a hypothesis explaining the phylogeny of various groups of animals. For the descent of one homologous group from another, the term *polyphyletic* has been coined. It remains to be seen whether the doctrine is of universal application or not. That homologous groups belong to different geological horizons, as stated under the fifth head, has been frequently demonstrated since the publication of the essay. That the sixth proposition is true in a certain number of cases is well known, and it follows that the seventh proposition is also true in those cases. The latter hypothesis, which was originally advanced by Professor Agassiz, is, however, only partially true, and the advance of paleontological study has not demonstrated that it has had a very wide application in geological time.

"A proposition which was made prominent in this essay was that the prevalence of non-adaptive characters in animals proves the inadequacy of hypotheses which ascribe the survival of types to their superior adaptation to their environment. Numerous facts of this kind undoubtedly indicate little or no activity of a selective agency in nature, and do point to the existence of an especial developmental force acting by a direct influence on growth. The action of this force is the acceleration and retardation appealed to in this paper. The force itself was not distinguished until the publication of the essay entitled 'The Method of Creation' [1871], where it was named growth-force, or bathmism. The energetic action of this force accounts for the origin of characters, whether adaptive or non-adaptive, the former differing from the latter in an intelligent direction, which adapts them to the environment. The numerous adaptive characters of animals had by that time engaged the attention of the author, and he found that they are even more numerous than the non-adaptive. Some of the latter were accounted for on the theory of the 'complementary location of growth-force.'"

We can only consider the 'law of acceleration and retardation.' Again it behooves us to seek his own definition:

"*a.* The succession of construction of parts of a complex was originally a succession of identical repetitions; and grade influence merely determined the number and location of such repetitions.

"*b. Acceleration* signifies addition to the number and location of such repetitions during the period preceding maturity, as compared with the preceding generation, and *retardation* signifies a reduction of the number of such repetitions during the same time.*

His meaning may best be inferred from his application to mankind. This was done in the following terms in 1872:†

"Let an application be made to the origin of the human species It is scarcely necessary to point out at the start the fact, universally admitted by anatomists, that man and monkeys belong to the same order of Mammalia, and differ in those minor characters, generally used to define a 'family' in zoology.

"Now, these differences are as follows: In man we have the large head with prominent forehead and short jaws; short canine teeth without interruption behind (above); short arms, and thumb of hand not opposable. In monkeys we have the reverse of all these characters. But what do we see in young monkeys? A head and brain as large relatively as in many men, with jaws not more prominent than in some races; the arms not longer than in the long-armed races of men, that is, a little beyond half way along the femur. * * * At this age of the individual the distinctive characters are therefore those of *homo*, with the exception of the opposable thumb of the hind foot, and the longer canine tooth. * * *

"Now in the light of various cases observed, where members of the same species or brood are found at adult age to differ in the number of immature characters they possess, we may conclude that man originated in the following way: that is, by a delay or retardation of growth of the body and fore limbs as compared with the head; retardation of the jaws as compared with the brain case, and retardation in the protrusion of the canine teeth."

There is good reason for thinking that fallacy is involved in this argument and that quite a different interpretation should be put on the evolution of the characters in

*Proc. Am. Phil. Soc., 1871; Origin of Fittest, p. 182.

†Penn. Monthly Mag., 1872; Origin of the Fittest, p. 11, 1887.

question. It is not the fore limbs that are retarded in man, but the hind limbs have become enlarged (compare the adult and the infant). There is not retardation of the jaws, but a special teleological adaptation. Man has for the most part at least discontinued the use of his teeth for warfare, and as a result of diminished use the canines have become reduced and the diastemata of the dental series been obliterated. The brain has grown after birth and become enlarged, and as a consequence the brain case has extended forward—the reverse of what occurs in the apes. Concomitantly with the diminished use of the teeth and jaws, the masseter and temporal muscles have become reduced, and the sagittal and lambdoidal ridges have consequently became atrophied. The ecarinate rounded voluminous calvarium is the result.

It has been claimed that the young of higher species 'are constantly accelerating their development.' In many, however, development is retarded, inasmuch as infancy and juvenility are prolonged far beyond the periods observed in our simian relatives.

Such examples as this give cause to believe that the 'law of acceleration and retardation' has been at least unduly extended. Acceleration and retardation are, however, to a large extent, terms which express facts of evolution; whether the word law is applicable may depend on the meaning one gives the word.

The transmission of acquired characters was one of the accepted and most cherished dogmas of Cope, and the belief in transmissibility of such characters is an essential of the creed of so many who have become his followers in America that a special school came into existence known as the Neo-Lamarckian and also as the American School. My own prejudices have inclined me to that school. Nevertheless, when I have divested myself of such prejudices as well as I could, I have been compelled to admit that the evidence of the heredity of acquired characters was rather weak. There was, indeed, evidence for, a well as against, but that against the doctrine of the transmissibility of acquired characters seems to be the most weighty.

It is to be understood that the acquired characters considered in this connection are such as have been developed during postnatal life as a result of endeavors of the animal or of the influence of external agencies. The evidence presented has been mostly in support of the contention that the characters acquired have been directly inherited by offspring, and consequently the transition from the form not possessing the character to one having it is rapid. The evidence adduced has not been conclusive, to say the least. There is, apparently, a germ of truth in the proposition that acquired characters are transmitted, but in a modified sense, and the case has been weakened rather than strengthened by the evidence offered.

The evidence for inheritance of acquired characters was frequently given by Cope and in his last published work—'The Primary Factors of Organic Evolution,'—he marshalled the testimonies of many witnesses with his accustomed skill. He evoked 'evidence from embryology,' 'evidence from paleontology,' 'evidence from breeding;' he considered the 'characters due to nutrition,' 'characters due to exercise of function,' 'characters due to disease,' 'characters due to mutilation and injuries,' and 'characters due to regional influence'; he inquired into 'the conditions of inheritance,' and he fought against the 'objections to the doctrine of inheritance of acquired characters.' I have gone over all this evidence and yet I have not been convinced that the contention has been sustained that character acquired during the external life of an animal are transmitted. Many cases are alleged to sustain the 'inheritance of charac-

ters due to mutilation and injuries.' Some of these may be considered as mere coincidences; others provoke skepticism for one reason or other. To discuss them would be out of place here. But at least we may meet evidence with counter-evidence.

On the one hand, all the data and experiments recapitulated in the cases enumerated concern only two, or at most very few, generations of the animals in question, and were within the compass of a single man's life-time.

On the other hand, we have data and observations of the most reliable nature, and of an extraordinary compass. These have resulted not from experiments for the determination of a specific question, but from observances of a religious character. They were really in the nature of surgical operations, but for our purpose may be looked upon as experiments and have the value of contrived experiments. In no other field has such a series of disinterested experiments been available. They were conducted on countless millions of mankind and for thousands of years. The subjects experimented upon were kept isolated from others alike by their own prejudices and the prejudices of their neighbors. Circumcision is the term applied to the experiments in question.

For about 4,000 years circumcision has been practiced on a gigantic scale. Every male child among the Jews was operated upon, not only in Palestine, but wherever representatives of the race had wandered and adhered to their religion; religion itself was involved in the operation and it was regarded as a holy rite; the most scrupulous attention was paid to details. The operation was performed eight days after birth, and consequently there could be no functional activity of the tissues concerned. But after 4,000 years the newborn boys of the race come into the world with the special integument developed as much as in those of other races. Even the principle of atrophy through disuse has not become manifest in the case.

Other evidence, it seems to me, is the result of confounding the potentiality of a function with its manifestation. I allude to one set of examples on account of the interest of the cases, and I do so with the deference due to the eminence and ability of the gentleman who has furnished the evidence. That evidence has been collected under the head of 'inheritance of characters due to the exercise of function.' The evolution of the American trotting horse was considered. It was recorded that "by 1810 the taste for trotting as a sport had * * * increased here, and in 1818 it became a recognized sport under specific rules." * * * "At the end of 1824, six years after the first accepted three-minute record, the record had fallen to 2:34." * * * "By 1848 the record was lowered to 2:29½; the next decade lowered the record five seconds." Finally, at the close of 1895, the record had been furthered lowered to 2:08¼. * * * It is deduced from these premises that "there is nothing whatever in the actual phenomena observed anywhere along the line of this development of speed that would lead us to even suspect that the changes due to exercise of function had *not* been a factor in the evolution." But to me it seems that there is no evidence to show that the speed attained was other than would have resulted from taking the same animals untrained and then speeding the last. The speed is, of course, simply the expression of functional adaptation, and the horses were selected merely because, by their manifestation, they showed that they had the coordination of structural and psychological characters needed for the manifestation of the function. The manifestation guided the breeder to the selection of the animals. The successful animals were the pick of thousands unknown to fame.

But there is much in the history of the development of animals that seems to lead to the belief that eventually modifications may be due in part to acts of representatives of the phylum to which they belong. It is difficult to believe that some structural features are simply the result of natural selection operating on chance variations. An application of the doctrine of chances to some such cases appears to be adverse to the conception that they represent the influence of natural selection unaided.

A feature characteristic of most cave animals of widely diverse groups and classes is the atrophy of the eyes, and it seems to be most logical to attribute this to disuse of those organs in remote progenitors, and to assume that the atrophy may have resulted from a failure of nourishment by the nutrient fluid of the organs on account of the loss of functional activity rather than to selection by nature of forms with successively diminishing eyes. The presence of eyes in most cases certainly would scarcely be an element of disadvantage to animals, and it may be allowable to invoke some other agency than chance selection. We may be justified in postulating that the continuous disuse of the organs would in time react on the nutrition of the parts affected, and finally atrophy or disappearance would result. Like explanation would be applicable to the innumerable cases of atrophy of parts known to the naturalist.

But if cessation of nutrition culminates in final atrophy, increased nutrition of parts may result in hypertrophy and increased nutrition may be the concomitant of increased activity of parts. The exercise of such parts continued for many generations may react on the organization and the progeny at length be affected thereby. Of such cases Cope adduced many examples. The feet of the horse line furnish illustrations. The existing horse has the median toes and hoofs greatly hypertrophied and the lateral ones atrophied, but the remote ancestors had feet of nearly the same general pattern as the rhinoceroses and tapirs. Atrophy of the lateral digits has progressed inversely to hypertrophy of the middle ones. An analogous line of development culminating in feet superficially much like those of the horse was followed by another quite remote family of hoofed mammals, the Prototheriids of South America.

The idea of acceleration and retardation were associated by Cope with the idea that the course of evolution was determined from the beginning of things, and that life, to use his own words, is '*energy directed by sensibility or by a mechanism which has originated under the direction of sensibility.*' He maintained that 'consciousness as well as life preceded organism,' and he called this conception 'the hypothesis of archæsthetism.' This idea I refer to especially because it was broached in his vice-presidential address, delivered at the meeting of the American Association for the Advancement of Science in Philadelphia in 1884.*

I am myself unable to comprehend consciousness except as a product or result of organization, and those who wish to learn more about Cope's views respecting the question must refer to one of his many papers.

Whatever may be thought of Cope's philosophical views, his presentation of them is always interesting and some of them are illustrated with a wealth of facts that renders his communications valuable as repertories of well digested information. His first special paper, on 'The Origin of Genera,' published as early as 1868, is especially noteworthy for the mass of morphological data contained in it and for the apt manner in which they are tabulated.

VIII.

I venture to conclude with some reflec-

* Origin of Fittest, p. 425.

tions on the rank that may be assigned to Cope in the world of science.

Among those that have cultivated the same branches of science that he did—the study of the recent as well as the extinct Vertebrates—three naturalists have acquired unusual celebrity. Those are Cuvier, Owen and Huxley.

Cuvier excelled all of his time in the extent of his knowledge of the anatomical structure of animals and appreciation of morphological details, and first systematically applied them to and combined them with the remains of extinct Vertebrates, especially the mammals and reptiles. He was the real founder of Vertebrate paleontology.

Owen, a disciple of Cuvier, followed in his footsteps, and, with not unequal skill in reconstruction and with command of ampler materials, built largely on the structure that Cuvier had begun.

Huxley covered as wide a field as Cuvier and Owen, and likewise combined knowledge of the details of structure of the recent forms with acquaintance with the ancient ones. His actual investigations were, however, less in amount than those of either of his predecessors. He excelled in logical and forcible presentation of facts.

Cope covered a field as extensive as any of the three. His knowledge of structural details of all the classes of Vertebrates was probably more symmetrical than that of any of those with whom he is compared; his command of material was greater than that of any of the others; his industry was equal to Owen's; in the clearness of his conceptions he was equalled by Huxley alone; in the skill with which he weighed discovered facts, in the aptness of his presentation of those facts, and in the lucid methods by which the labor of the student was saved and the conception of the numerous propositions facilitated he was unequalled. His logical ability may have been less than that of Huxley and possibly of Cuvier. He has been much blamed on account of the constant changes of his views and because he was inconsistent. Unquestionably he did change his views very often. Doubtless some of those changes were necessitated by too great haste in formulation and too great rashness in publication. The freedom to change which he exercised, and which was exercised too little by at least one of his predecessors, was an offset to his rashness. He exercised a proper scientific spirit in refusing to be always consistent at the expense of truth.

His reputation at present is much inferior, at least among the people at large, to those of the men with whom he has been compared. Immediate reputation depends on various circumstances, some of which are quite adventitious, and it is often long before men find their true levels. It is scarcely premature to prophesy that Cope's reputation will grow and that in the future history of science his place will be at least as large as that of any of his predecessors.

THEO. GILL.

WASHINGTON.

EXPERT TESTIMONY.*

IT will be remembered that a would-be facetious barrister once remarked that prevaricators might be properly arranged in an ascending series, to wit: ordinary fibbers, liars and experts; an arrangement which I fear meets with the approval of many members of the bench and bar today. The cause for such harsh classification is not so very far to seek. It is based upon ignorance on the part of the bar, and at times upon what is worse than ignorance on the side of the 'expert.' With the culpable acts of the pseudo scientist we cannot waste our time. That he merits

* Address of the Vice-President and Chairman of Section C (Chemistry) at the Detroit meeting of the American Association for the Advancement of Science.

prompt condemnation is axiomatic, but a word is wanted touching upon what may be termed the ignorance of the Court.

"When I take my place upon the witness stand," said a prominent toxicologist once to me, "I can never predict in what shape I shall be upon leaving it;" a feeling with which most of us can, I fancy, sympathize pretty keenly.

Is it that we fear exposure of the weak points in our professional armor? Do we dread to say in public, "I do not know?" Hardly that, I take it. We are now possessed of so very little of that which one day may be known that no true scientist hesitates for an instant to plead legitimate ignorance. What really troubles us upon cross-examination is that the Court does not speak our language, a language often quite difficult of direct translation; that it is but rarely schooled in the principles of our science; and that, in consequence, it frequently insists upon categorical answers to the most impossible kind of questions.

The hypothetical questions showered upon the expert witness are sometimes veritable curiosities, so peculiar are they in their monstrosity. Who among us but has felt that the layman, who has simply to testify to observed facts, has an easy time of it, indeed, when compared with him from whom there is expected an opinion under oath?

All scientific men are willing and anxious to have their work scrutinized carefully by their peers; but to be exposed to the one-sided criticism frequently encountered at the bar is quite another matter; for it must be remembered that, after the adverse counsel has opened up what appears to be a glaring inconsistency in the testimony, the re-direct examination may utterly fail to repair the breach, because of a lack of familiarity with a technical subject on the part of the friendly attorney.

This leaves the witness in the uneviable position of disagreeing with the general drift of his own testimony, while it deprives him of suitable means of insisting upon its revision and correction.

According to the writer's view, there is but one way to escape such dilemma, and that is by direct and immediate appeal to the Judge, urging that the oath taken called for a statement of the whole truth, and not the misleading portion already elicited.

To illustrate how serious a matter the partial testimony of an expert witness may be, and to show also to what extent lawyers may go who look only to the winning of their causes, permit me to refer to an already reported poison case in which I was employed by the people. It may be roughly outlined as follows:

Much arsenic and a very little zinc were found in the stomach.

The body had not been embalmed, but cloths wrung out in an embalming fluid containing zinc and arsenic had been spread upon the face and chest.

Medical testimony showed that no fluid could have run down the throat. Knowing the relative proportions of zinc and arsenic in the embalming fluid, the quantity of arsenic found in the stomach was twelve times larger than it should have been to have balanced the zinc also there present, assuming them to have both come from the introduction of the said embalming fluid by cadaveric imbibition. Other circumstantial evidence was greatly against the prisoner.

At the time of my appearing for the people, on the occasion of the first trial of the case, my direct testimony brought out very strongly the fact that a fatal quantity of arsenic had been found in the stomach, but no opportunity was given me to testify to the presence of the zinc found there as well, although the fact of its existence in the body was known to the prose-

cution through my preliminary report. Through ignorance of the nature of such report on the part of the defence, no change was made in the character of the testimony during the cross-examination, and I was permitted to leave the witness stand with a portion of my story untold. No witnesses were called for the defence, and the case was given to the jury with the darkest of prospects for the prisoner.

For many reasons, unnecessary to recount here, I was distinctly of the opinion that murder had been committed, but I felt nevertheless that common justice demanded that the prisoner should have been entitled to whatever doubt could have been thrown upon the minds of the jury, no matter how far-fetched the foundations for such doubt might have been.

The first trial having resulted in a disagreement of the jury, I was pleased to learn, before the second hearing of the case began, that the defence was prepared to go into the question of the embalming fluid; for the responsibility of permitting only a part of what I knew to be drawn from me, to the entire exclusion of the remaining portion, was greater than I wished to assume. The nature of my report to the Coroner having been established, and certain opinions relating thereto having been fully ventilated, the jury were possessed of 'reasonable doubt' and acquitted the prisoner. What now were the duties of the expert upon the occasion of the first trial of this case and how should he have construed the meaning of his oath?

One eminent legal light, to whom the question was referred, held that the expert was distinctly the property of the side employing him, and that his duty was simply to answer truthfully the questions put to him, without attempting to enlighten the Court on facts known to him, but not brought out by the examination, no matter how vital such facts might be.

Another held that although the above course would be proper in a civil case, yet, in a matter involving life and death, the witness should insist upon the Court becoming acquainted with his whole story. Do not such differences in legal opinion make it very desirable that the expert, at least in capital cases, should be an employee of the bench rather than of the bar, in order that whatever scientific investigations are made may be entirely open to public knowledge and criticism?

Although the expert should earnestly strive to have what he has to say presented in the best form, he must remember that to secure clearness, particularly before a jury, technicalities should be reduced to a minimum. To a degree they are unavoidable, but let them be as few as possible. Illustrations should be homely and apt; capable of easy grasp by the jury's minds, and, if possible, taken from scenes familiar to the jury in their daily lives.

It is an unfortunate fact that the expert must be prepared to encounter in the court room not only unfamiliarity with his specialty, but also deep-rooted prejudices and popular notions hoary with age and not to be lightly removed from the mind by the words of a single witness. As President Jordan has well said, "There is no nonsense so unscientific that men called educated will not accept it as a science;" and, let me add, they will calmly attempt to shove the burden of proof upon the scientific man who is opposed to their views. Sanitary experts, in particular, run up against all sorts of popular superstitions and are inveighed against as 'professors' by those who consider themselves the 'practical' workers of the time; and, let it be noted, the burden of proof is uniformly laid upon these 'professors'' shoulders, while the most astounding and occult statements made by the 'practical' men may be received without verification.

One source of trouble, which perhaps is

peculiar to the water expert, lies in the impossibility of utilizing analytical results such as were made many years ago.

Those who are not chemists fail to grasp the fact that the examinaton of water may not be looked upon from the same point of view as the analysis of an iron ore. The statement that water analysis is of recent birth, and that it is yet in its infancy, is hard for them to appreciate, holding, as they naturally do, that what was true twenty years ago must be true to-day, if science does not lie.

A pit into which many an expert witness falls is prepared for him by insidious questions leading him to venture an opinion on matters outside of his specialty. It is a fatal error to attempt to know too much. Terse, clear answers, well within the narrow path leading to the point in question, are the only safe ones; and when the line of inquiry crosses into regions where the witness feels himself not truly an expert, his proper course is to refuse to testify outside of the boundaries of his legitimate province.

Unfortunately, the expert is as often invited to take these collateral flights by the side employing him as by the opposition. Affidavits in submitted cases are commonly written by the lawyers and not by the expert, although they are, of course, based upon his reports. In the strength of his desire to win the case, the lawyer often prepares a much stronger affidavit than his witness is willing to swear to.

The writer has had no little difficulty just at this point, and has had plenty of occasion to observe the irritation displayed by counsel upon a refusal to endorse statements which have been 'too much expanded.'

Every expert witness, especially in his early cases, is sure to have adverse authorities quoted against him; therefore it behooves him to be so familiar with the literature of his subject as to be capable of pointing out that such and such a writer is not up to date, or that such and such a passage, if quoted in full, would not bear the adverse construction that its partial presentation carries. When the expert reaches a position of such prominence that he can state a thing to be so because he says it, irrespective of whatever may be written on the subject to the contrary, his course then is greatly simplified; but long before he attains that altitude he will have put himself upon record in many cases, and happy for him if the record so made be such as cannot be quoted to his disadvantage.

"If I had only not written my first book," is the reflection of many a distinguished author; while one of the great masters of music, referring to an opera, said: "It is one of my early crimes."

Above all things, the expert should "provide things honest in the sight of all men."

It is well for him to be deeply interested in his case, to feel in a measure as if it were his own, but it is unwise in him to become so partisan as to let his feelings affect his good judgment, and it would be indeed criminal should he permit his interest in any way to contort the facts.

Before the case is brought to a final hearing, it may be apparent that experiments before the Court are possible and they may be demanded by the counsel in charge of the case. If such experiments be striking, easy of execution, and not too long, by all means make them.

Practical illustrations, particularly such as involve some fundamental principle, have great weight with the Court; but these illustrations must not be such as would turn the court room into a temporary laboratory and involve the loss of much time in vexatious waitings.

Such experiments as are determined upon should be thoroughly rehearsed beforehand, no matter how simple they may be; for, of

all failures, the court-room experiment which declines to 'go off' is perhaps the most dismal.

This brings to mind a kindred topic upon which there should be a word of caution; laboratory experiments which work to perfection may utterly fail when expanded to commercial proportions, so that it is wise to bear in mind the danger of swearing too positively as to what will happen in large plants, when the opinion is based only upon what is observed to occur upon the smaller scale. Like conditions will, of course, produce like results, but it is marvellous how insidiously unlooked-for conditions will at times creep into one's calculations, and how hard it is even to recognize their presence.

When preparing his case for presentation, the expert often errs in not dwelling more largely upon certain points because he thinks them already old and well known. To him they may be old, but to the public they may be of the newest. Not only is the public unequally posted with the specialist, but what it once knew upon the subject may have been forgotten. Is is well, therefore, to insert, in a special report, matters that would be properly omitted from a paper prepared for a professional audience.

Sanitary problems are of especial interest to the public, but the amount of ignorance, or rather false knowledge, displayed concerning them is surprising and often difficult to combat. The sanitarian is not unfrequently called upon suddenly to defend a position involving complex statistics; and, because the data cannot be forthwith produced, the inference is drawn that his points are really without facts to support them and that they are consequently not well taken.

Long before he gets into Court, particularly if the time for preparation of the case be short, the expert may well 'pray to be delivered from his friends.' He may receive a peremptory order by telegraph to 'determine the mineral qualities of this rock,' when the telegram should have read 'Assay this ore for silver;' and later it may be a matter of surprise that a quantitative knowledge of the copper present was not obtained while passing along the line for the determination of the silver; for it is generally not known that the complete analysis of anything is quite rare and correspondingly tedious and expensive.

Toxicologists who hear me may call to mind some case involving a search for the presence of an alkaloid, strychnia for example, during which search the District Attorney, in his eagerness for information may have asked to know what the indications were as to the presence of the poison, at a time when the extraneous organic matter was not nearly removed. He may have wished no final report, but only the simple probabilities, whereon to base a possible arrest. Such requests are very common, and are akin to a demand for a proof of the pudding during the early baking, when we all know that such proof comes at a much later stage of the proceedings.

Finally, "When doctors disagree who shall decide?"

This question is often very vigorously settled by the jury, as was instanced in a recent celebrated murder trial in New York City. In that case what the experts had to say on either side was simply thrown overboard as a whole, and the finding was based upon the testimony of the remaining witnesses.

What can be said upon this question of the disagreement of expert witnesses? First, it must be noted, they are far from being the only class of people who fail to agree, and that too on very important subjects. Do my hearers think it would be a very difficult task to find a small army of men who would testify very variously and very posi-

tively upon questions of politics or religion? Would it be hard to find 'good men and true' who would give under oath greatly differing opinions concerning the propriety of instituting free trade or establishing an inheritance tax? Experts are subject to the same errors of judgment as befall the rest of professional humanity, and when their opinions clash they are entitled to the same respect that we grant to the members of the bench when they hand down the decision of a divided Court.

One fruitful opportunity for disagreement always arises when questions are brought into Court touching upon matters newly discovered and apart from the well beaten path of common professional knowledge. Doubt is often left upon the minds of those seeking the light, even when the testimony is given by the specialist who originally developed the new point in question, for one cannot be expected to be thoroughly educated in that which he has himself but recently discovered.

Many of us have dreaded to see the 'ptomaines,' or putrefactive alkaloids, make their way into Court with their mystifying influences upon Judge and jury and their tendency to protect crime. Now they are in, what is to be the end? Even with no 'Ptomaine theory' possible, the ptomaine form of argument is not unknown. The writer was once asked in an arsenic case whether he was willing to swear that at some future time an element would not be discovered giving the stated reactions now called arsenical. Such nonsense is, of course, instituted to impress the jury, and is suggested by similar questioning in the alkaloid cases.

A recent and somewhat amusing instance arose from an attempt to introduce the rather new conception of 'degeneracy' into a murder trial. The defence sought to show that the prisoner was a 'degenerate' and offered expert testimony as to the meaning of the term and as to the signs whereby such a condition was to be recognized, whereupon the prosecution called attention to the fact that the defendant's experts themselves exhibited every one of the signs in question.

Having said all that he was to say, and having stated it to the best advantage, should the expert depend upon the stenographer so recording it as to allow of its being used in future without correction? Decidedly not.

The average stenographer is unfamiliar with technical terms, especially such as are chemical, and the witness who fails to supervise the minutes may find out later that he has sworn to a most remarkable array of 'facts.' The writer once discovered that he had recommended, as a very efficient method of purifying a city water, the filtering of the entire supply 'through a layer of black mud.' Not to take your time further, let us summarize what has thus been briefly said:

The expert witness should be absolutely truthful, of course; that is assumed, but beyond that he should be clear and terse in his statements, homely and apt in his illustrations, incapable of being led beyond the field in which he is truly an expert, and as fearless of legitimate ignorance as he is fearful of illegitimate knowledge.

Mounting the witness-stand with these principles as his guide, he may be assured of stepping down again at the close of his testimony with credit to himself and to the profession he has chosen.

CURRENT NOTES ON ANTHROPOLOGY.

ARAUCANIAN STUDIES.

DR. RODOLFO LENZ continues his excellent studies on the Araucanian dialects and folk-lore, in the 'Anales de la Universidad

de Chile.' His last contribution embraces seven semi-mythical tales in the Pehuenche dialect, the original text and a Spanish translation. They offer much curious material, and often leave it doubtful whether the story is of native origin or borrowed from European sources. The first, for example, tells of a dead lover who came from his grave to claim his bride and carried her to his tomb. In spite of the striking similarity of this to the legend embodied in Bürger's ballad 'Lenore,' the editor believes it to have been from native sources.

Unfortunately, like so many other tribes, the Araucanians were little studied by the early settlers, and the knowledge we have of their mythology is vague and slight. Dr. Lenz very properly observes that it is all the more important to collect what still survives in their songs and stories; and, it may be added, the scholarly manner in which he presents his researches to the reader renders them models of work of this kind.

THE 14TH REPORT OF THE BUREAU OF ETHNOLOGY.

THIS report (for 1892–93) has just been distributed. It is in two parts or volumes counting up to over twelve hundred pages! The contributions are three in number, the first an exceedingly interesting paper by Mr. James Mooney on the ghost dances of our Western tribes; the second a study of the Menomini Indians, by Dr. Walter J. Hofman, containing a mass of accurate observations; and the third an erudite treatise on the expedition of Coronado to New Mexico in 1540, by Mr. George Parker Winship.

It is needless to dwell on the value of these contributions to the history and ethnography of our country. Every future student of these subjects will owe a debt to this and previous reports of the Bureau. No series of publications by our government has been edited with more conscientious care, and none can show a list of articles of a higher class, or of more permanent importance, than the Bureau of Ethnology. It should be a matter of patriotic pride, based on the recognition of solid merit, for the government to render liberal aid to this scientific department and increase the means of its usefulness.

NOTES ON INORGANIC CHEMISTRY.

A LECTURE by Professor William Crookes on 'Diamonds' was delivered June 11, 1897, at the Royal Institution. It has been reprinted in the *Chemical News* and is perhaps the best brief treatise on the diamond ever written. The latter part of the lecture was devoted to the origin of the diamond as illustrated by the diamond 'pipes' of the Kimberley field. According to Professor Crookes the diamonds crystallized out of molten iron containing carbon in solution and at sufficient depth below the surface to give great pressure. Water finding its way down to this iron, the gas generated bored out the 'pipes' which were, "at the subsidence of the great rush, filled with a water-borne magma in which rocks, minerals, iron oxid, shale, petroleum and diamonds are churned together in a veritable witch's cauldron," a mud volcano. "It may be that each volcanic pipe"—of the South African fields—"is the vent for its own special laboratory—a laboratory buried at vastly greater depths than we have reached or are likely to reach—where the temperature is comparable with that of the electric furnace; where the pressure is fiercer than in our puny laboratories and the melting point higher; where no oxygen is present, and where masses of carbon-saturated iron have taken centuries, perhaps thousands of years, to cool to the solidifying point. Such

being the conditions, the wonder is, not that diamonds are found as big as one's fist, but that they are not found as big as one's head. The chemist arduously manufactures infinitesimal diamonds, valueless as ornamental gems; but Nature, with unlimited temperature, inconceivable pressure and gigantic material, to say nothing of measureless time, produces without stint the dazzling, radiant, beautiful crystals I am enabled to show you to-night."

PROFESSOR MOURELO, of Madrid, has investigated the preparation of a strongly phosphorescent strontium sulfid. The pure compound shows no phosphorescence, but the presence of a small quantity of alkali seems necessary, and a trace of subnitrate of bismuth is of advantage. When the mass which has been strongly heated is very slowly cooled, it shows after the action of even very little light, a strong phosphorescence. This property is lost on pulverization, but may be restored by long heating with starch.

IN the *Zeitschrift für Angewandte Chemie* Th. Bokorny gives the results of a study of the antiseptic action of various substances. A culture medium of half per cent. egg albumen or peptone, with one-tenth per cent. potassium phosphate, two-tenths per cent. magnesium sulfate and a trace of calcium chlorid was infected with the bacteria of decay, and after addition of the substance to be tested, placed for several days in an incubator. Among inorganic compounds silver nitrate and mercuric chlorid have about the same value, 0.002 %, killing all organisms in two days. The antiseptic limit with silver nitrate is 0.0002 %; with mercuric chlorid 0.001 to 0.0002 %. Copper sulfate is nearly as active, 0.005 % killing all organisms in twenty-four hours, and 0.001 % preventing decomposition. Zinc sulfate 0.01 % kills infusoria in eighteen hours, but 0.1 % is not completely antiseptic, while cadmium sulfate toward algæ and infusoria is weaker than the zinc salt, but toward bateria stronger, 0.02 % being antiseptic. Lead acetate and nitrate in 0.1 % solution only delay decay, while it is prevented by the same strength of iron sulfate solution. The fluorids are not strong antiseptics, the limits being for hydrofluoric acid 0.02 %, barium fluorid 0.3 %, aluminum fluorid 0.1 %, calcium fluorid 0.03 %, ferric fluorid 0.06 %, magnesium fluorid 0.05 %. Ammonium fluorid 0.1 % is without action, but sodium fluorid 0.1 % is antiseptic; potassium fluorid is rather more active. J. L. H.

NOTES ON ENGINEERING.

A COMMITTEE of the British Institution of Civil Engineers, appointed a year ago or more, have reported the following recommendations on steam-engine efficiency, and they have been adopted by the Council:

(1) That the statement of the economy of a steam-engine in terms of pounds of feed-water per I.HP. per hour is undesirable.

(2) That for all purposes except those of a scientific nature it is desirable to state the economy of a steam-engine in terms of the thermal units required per I.HP. per hour (or per minute), and that if possible the thermal units required per brake HP. should also be given.

(3) That for scientific purposes the thermal units that would be required by a perfect steam-engine working under the same conditions as the actual engine should also be stated.

The proposed method of statement is applicable to engines using superheated steam as well as to those using saturated steam, and the objection to the use of pounds of feed-water, which contain more or less thermal units according to conditions, is obviated, while there is no more practical difficulty in obtaining the thermal units per I.HP. per hour than there is in arriving at the pounds of feed-water.

For scientific purposes the difference in the thermal units per I.HP. required by the perfect steam-engine and by the actual engine shows the loss due to imperfections in the actual engine.

A further great advantage of the proposal is that the ambiguous term 'efficiency' is not required.

IN the contest which has now been so long

waged over the disputed originality of invention of the high explosive 'cordite,' Mr. Hiram Maxim, one of the contestants, and one in whom his fellow-countrymen in the United States feel much interest, is, for the time at least, defeated. Referring to this important case, one of the English technical journals, *Industries and Iron*, makes the following remarks: "The appeal of the Maxim-Nordenfelt Guns and Ammunition Company against the judgment delivered by Mr. Justice Wright in the Cordite case has been, as was generally anticipated would prove to be the case, against the appellants. The judgment of the Court was couched in somewhat uncompromising language, and it is doubtful whether the Maxim-Nordenfelt Company will consider it advantageous to carry the matter any further. Although the Court is no doubt perfectly right in its definition of the nature of the invention comprised in Mr. Maxim's patent, as against that of Sir Frederick Abel and Professor Dewar, none can deny the fact that Mr. Maxim was the undoubted pioneer in smokeless powders as we now know them, and it will be conceded by most that the recent decision involves a certain degree of hardship. Mr. Maxim's invention of a smokeless powder was not an accidental discovery; he was forced into the course of the investigation he took up by the necessity of procuring a powder which would be suitable for the rapid-firing gun which he had invented. He found that the use of the ordinary powder practically destroyed the utility of his gun, by surrounding it with such clouds of smoke that it was impossible to take aim. Mr. Maxim then deliberately set himself to the purpose of producing a powder which should be almost, if not altogether, smokeless. In this he was absolutely successful, and he has only shared the fate of many other inventors in seeing the fruits of his invention taken away from him through legal technicalities."

A FOREIGN exchange makes the following very unequivocal statement relative to our later systems of procedure in the Patent Office. A recent change in the law prevents any such delay, whether intended or otherwise on the part either of the holders of the patent or of the officer of the Patent Office: "The amazing circumstances which characterized the issue of the Berliner patent, to which is due the controlling interest in the United States of the Bell Telephone Company, have been paralleled by the well-known Bradley patents, which are now creating a good deal of stir among the manufacturers of aluminium and carbide of calcium. In the former case, the patent lay in the Patent Office for a period of no less than thirteen years before it was formally issued to the public. The Bradley patents were similarly interred for nine years before they were resurrected for the purpose of being used against the Pittsburg Reduction Company. It must be a gratifying reflection to those interested in patents and inventions in the United States that the singular course of procedure suggested by the foregoing instances will not be allowed to characterize the American Patent Office much longer. On January next the new regulations come into force, by which it is enacted that the issue of a patent shall be compulsory within a certain definite period from the date of application; and, under these circumstances, it seems likely that the familiar legend 'Patent applied for' on American manufactures will shortly become effete."

R. H. T.

SCIENTIFIC NOTES AND NEWS.

IN view of the International Congresses of Geology and Medicine, meeting in Moscow during the present month, the tenth meeting of Russian men of science and physicians, which was to have been held at Kief during the same month, has been postponed until 1898.

THE President of the local executive commit-

tee of the British Association for the Advancement of Science announces that McMaster University, a college residence, has been selected as the headquarters of the American Physiological Society during the Toronto meeting of the British Association. Rooms and board may be obtained there at $1.50 to $2.00 per day.

THE French Association for the Advancement of Science will meet next year at Nantes. At the meeting being held this week at St. Étienne the public lecture was to have been given by M. Gariel, on the Röntgen rays. Subjects proposed for special discussion were: Section of Physics, 'Atmospheric Electricity;' Section of Meteorology, 'The Study of Clouds;' Section of Geology, 'The Formation of the Fossiliferous Basins of the Central Plateau;' Section of Hygiene, 'The Part played by Leaves of Absence from School in the Spread of Contagious Diseases.'

A MEETING of the Council of the Australasian Association for the Advancement of Science was held at the Royal Society's House, Sydney, on June 17th, with fifteen members in attendance. Letters were read from the Royal Society of Tasmania, the Melbourne Branch of the Royal Geographical Society and the Medical Society of Queensland, suggesting a memorial to the late Baron von Müller. A preliminary committee was appointed to make arrangements for the meeting to be held at Sydney in January next. A large number of papers have been promised for the several sections; Section G., Economic Science and Agriculture, leading with twenty-eight papers, followed by Section F., Ethnology and Anthropology, and Section J., Mental Science and Education, each with eighteen papers.

JAMES HAMMOND TRUMBULL, LL.D., the well-known philologist, died in Hartford, Conn., August 5th, aged seventy-six years. For many years he paid especial attention to the subject of the Indian languages of North America. He was a member of the National Academy of Sciences and of many other learned societies.

WE regret also to record the death of Captain Bertram Lutley Sclater, son of the eminent zoologist, who died at Zanzibar on July 24th, at the age of thirty-one years, of fever contracted while making surveys and explorations in British Central Africa; of Dr. Golowkinskie, formerly professor of mineralogy and geology in the Universities of Kasan and Odessa, at Kastel, on June 9th, and of M. Étienne Vacherot, formerly professor of philosophy and assistant to Cousin, and the author of numerous contributions to philosophy, political economy and science, at the age of eighty-six years. M. Vacherot took a prominent part in French politics, having been one of the Mayors of Paris during the siege.

DR. WILHELM THIERRY PREYER, whose death we recently noticed, was a man of unusual versatility and originality. He was born in Manchester, England, in 1841, and received his education in that country until he was sixteen years old. After studying at various German universities and at Paris, he qualified as docent in the University of Bonn, first in zoology and afterwards in physiology. His first work was in zoology, and he published several books treating of problems in which zoology and physiology are both concerned, such as 'The Struggle for Existence' (1869), 'Hypotheses regarding the Origin of Life' (1875), and 'Spontaneous Generation and the Conception of Life' (1879). In 1869 Preyer was made professor of physiology at Jena, but removed to Berlin in 1880 and qualified as docent in the University. He was not promoted to a professorship at Berlin and removed to Wiesbaden in 1893. In addition to the works mentioned above, Preyer wrote numerous articles and at least two volumes concerning the general problems of science, partly of a popular character. He published an 'Elements of General Physiology' in 1883 and had earlier published a book on the 'Five Senses of Man,' translated into English in the International Scientific Series. He also made many contributions to the physiology of the senses and to experimental psychology, and was one of the Board of Editors of the *Zeitschrift für Psychologie.* His volume on 'The Child's Mind' (1879) has been the starting point of numerous similar observations, though it is interesting to note that the first scientific biography of a child was written by Darwin. Preyer's versatility is

further illustrated by the fact that his last volume was on graphology.

THE statue of Darwin at the entrance to the public library and museum of Shrewsbury, to the erection of which, by the Shropshire Horticultural Society, we have already called attention, was to have been unveiled on August 10th. The statue, in bronze, is by Mr. Horace Montford.

ON the eleventh of July a monument was unveiled at Bresches to Velpeau, the eminent French surgeon.

A MEDALLION portrait of Pasteur, by M. Patey, after the medal by M. Roty, has now been placed on the wall of the École Normale Supérieure, the site of the former laboratory of Pasteur. The inscription previously inscribed on the tablet reads:

ICI FUT LE LABORATOIRE DE PASTEUR.
1857.—Fermentations.
1860.—Générations spontanées.
1865.—Maladies des vins et des bières.
1868.—Maladies des vers à soie.
1881.—Virus et vaccins.
1885.—Prophylaxie de la rage.

THE position of Assistant Chief of Division of Soils, Department of Agriculture, salary $1,800 per annum, is to be filled by the Civil Service Commission. Applicants must submit, not later than September 1st, original essays, either printed or in manuscript form, consisting of not less than 5,000 words, and containing a thorough treatment of the subject, 'Environment as affecting the yield, quality and time of ripening of crops.'

DR. JOHANNES MARTIN has been appointed Director of the Natural History Museum of Oldenburg, and Dr. Philippi, assistant in the Nattural History Museum in Berlin.

THE Prince of Wales has been elected a fellow of the Royal College of Physicians, London, or, as the English papers put it, he has complimented the profession by accepting the fellowship. As a non-medical fellow, the Prince has only three predecessors, the Marquis of Dorchester in 1658, the Duke of Manchester in 1717, and the Duke of Richmond in 1729.

THE Legislature of Uruguay has conferred honorary citizenship and the sum of $10,000 on Dr. Sanarelli as a recognition of his discovery of the yellow fever microbe.

THE Faculty of Philosophy of the University of Strasburg has conferred the honorary degree of Doctor of Philosophy upon Professor Flinders Petrie, the celebrated Egyptologist.

AT the annual general meeting of the British Medical Association, on July 27th, the gold medals for distinguished merit were awarded to Sir Walter Foster and Mr. C. G. Wheelhouse. The Stewart prize was awarded to Dr. G. S. Woodhead, and the Middlemore prize to Dr. Alexander Hill Griffith.

THE Yerkes Observatory of the University of Chicago will be dedicated on October 1st. The program is not yet announced, but it is planned to hold a series of conferences as part of the ceremonies, and it is hoped that a large number of astronomers and other men of science will be present.

REPLYING recently to a committee asking for the earlier opening of Kew Gardens, Mr. Akers-Douglas said the *raison d'être* of the existence of Kew Gardens was the valuable scientific work it did, and he could not be expected to do anything in the way of extending the hours during which the Gardens were open to the general public if it would interfere with that work. The financial question did not weigh with him at all, for if he were convinced that the interests of science would not suffer by the earlier opening he should endeavor to persuade the Treasury to grant any extra money required. The sole question for consideration was whether the interests of science could be combined with the desire of the people for the earlier opening, and he regretted to say that the scientific men whose opinions he had obtained were entirely opposed to the proposal. From a scientific point of view the experiment had not been a success in Edinburgh, and they had no reason to anticipate any better result at Kew.

WE have published several notices of the expedition in Central Asia under the direction of the Swedish traveler, Dr. Sven Hedin. He is now preparing the results of his explorations for publication, and is expected to present these before the Royal Geographical Society of London

early in the autumn. The Russian Geographical Society will confer its gold medal upon him.

IT is stated in *Natural Science* that under the directorship of Dr. T. Kochibe, the Geological Survey of Japan has been making good progress, and the staff has been increased. There has for some time been accumulating a collection chiefly illustrative of practical geology, and it is now proposed to build a proper geological museum in Tokyo. A short time ago some valuable phosphatic beds of Tertiary age were discovered along the northeast shore of the province of Kyushu, and Dr. Tsuneto, of the Agronomic division of the Survey, has been experimenting with the material so as to make it available for the small Japanese peasant farmers to use as manure. The organic remains in the deposit are those of marine invertebrates.

DR. W. L. ABBOT, of Philadelphia, who has made valuable donations to the Smithsonian Institution, has now given a collection of birds from the Malayan peninsula containing 1,100 birds representing over 200 species.

STANFORD UNIVERSITY has been given by the brother of the late Senator Stanford, now residing in Australia, a collection of books relating to Australia, including especially works on the geography, geology and anthropology. It consists of 2,500 bound volumes and 3,000 pamphlets.

MR. FORTESQUE FLANNERY, M. P., has announced his intention to move in the House of Commons: "That in the opinion of the House it is desirable that a department of public health be constituted and that the same be under the charge of a responsible Minister having a seat in Parliament."

A COMMITTEE, consisting of Lord Crawford, Sir Edward Thompson, Sir Benjamin Stone, Professor Meldola, Captain Abney and others, has been appointed for the purpose of forming a National Photographic Record Association, the object of which is to be the collecting and making photographic historical records of the British Isles.

AN International Congress is being arranged at Paris for the discussion of the means of preventing fires in theatres and other places of public resort.

THE New York *Evening Post* states that an extensive robbery of art works and other articles of great value has taken place at the museum of the Canton of Vaud. The museum is located in the College near the Cathedral of Lausanne, and contains natural-history collections from Aventicum and Vidy, the ancient Lausanne, and interesting antiquities from lake-dwellings, coins, medals, etc. It also contains the Cantonal Library of 60,000 volumes.

A CURIOUS robbery has occurred in Paris, a number of rabbits inoculated with the germs of diphtheria, cholera, typhus, etc., having been stolen from the Aubervilliers Hospital. These are thought to have been sold to dealers, and there was a general panic in Paris among those who had eaten rabbit!

THE British Home Office will only allow five pounds of carbide of calcium to be kept without a license. It must then be kept in separate, substantial, hermetically closed metal vessels containing not more than one pound each.

THE New York State Commission on Voting Machines, consisting of Philip T. Dodge, Professor R. H. Thurston and Mr. H. de B. Parsons, held their first meeting at Albany on July 10th, for the examination of machines to be adopted by the State.

ARRANGEMENTS have been made in Boston to give members of the fire department instruction in the nature of electricity and the uses of electrical appliances.

A NEW fire-proof building will be erected for the collections of the Pathological Institute at the University at Berlin.

AT its meeting in Washington in May, 1897, the American Physiological Society appointed a committee to consider whether the time had come for the publication of an American Journal of Physiology. The committee have reported in favor of the plan and it will undoubtedly be adopted at the next meeting of the Society. The journal, which will be devoted to investigations in physiology and allied sciences, will probably begin publication in January next and will be edited by a committee of the Society, with Dr. W. T. Porter, Harvard Medical School, as Secretary.

THE *American Naturalist* has been purchased

from the estate of the late Professor Edward D. Cope and will, beginning with the next number, be edited by Dr. Robert P. Bigelow, instructor in biology in the Massachusetts Institute of Technology, assisted by an editorial committee and a board of associate editors whose names are not yet announced.

THE Zoological Society of Tokyo has begun the publication of *Annotationes Zoologicæ Japonensis*, under the editorship of Professor K. Mitsukuri, intended for contributions shorter than those contained in the Journal of the University. Professor Mitsukuri contributes an interesting introduction on the development of zoology in Japan, making due acknowledgment of the great services of Professors Morse and Whitman.

WE have received the first number of the second volume of the Bulletin of the Pará Museum of Natural History and Ethnology. The number, published in May of the present year, is largely devoted to the somewhat belated report of the director, Dr. Emilis A. Goldi, for 1895. There are attached to the museum a Zoological Garden and a Botanical Garden, a Library and a Meteorological Bureau. Numerous additions to these various institutions are reported during the year, the annual appropriation for the museum in 1895 being $70,000, and $12,000 each for the zoological and botanical gardens. The museum is visited daily by between 500 and 600 persons. The Bulletin further contains an account of an expedition, chiefly for archæological research on the Rio Maracá by A. P. de Lima Guedes, and four scientific papers.

THE manuscripts of the late Julius Sachs, the eminent botanist, will be edited by Professor Noll, of Bonn.

D. APPLETON & CO. announce that they will have ready for publication in the autumn the biography of Huxley prepared by his son.

LONGMANS, GREEN & CO. will shortly publish a new edition of 'Ancient Stone Implements, Weapons, and Ornaments of Great Britain' by Sir John Evans, President of the British Association. The work will be thoroughly revised, as much new material has been discovered since the first edition was published in 1872.

THE Civil Tribunal at Paris dismissed, on July 22d, the claim for 5,000f. damages preferred by the publisher of the French translation of Dr. Nansen's book against the *Correspondant*, in which Mme. Marie Dronsart reviewed Dr. Nansen's career and gave many extracts from the English version of his book.

PROFESSOR R. LYDEKKER contributes to the issue of *Nature* for July 15th an extended article entitled 'Species and Subspecies,' based upon the articles contributed to this JOURNAL by the Hon. Theodore Roosevelt and Dr. C. Hart Merriam. Professor Lydekker concludes his article with the following suggestion: "The question of the distinction between species and subspecies is undoubtedly one bristling with difficulties, and it is therefore one which in many cases is incapable of being definitely settled by an individual opinion. Although personally convinced of the advisability of using specific names in a wide sense, and employing trinomials for the designation of the nearly related forms, it may be suggested that an international committee of zoologists should be formed to discuss the question in all its bearings. Needless to say, such a committee should include representatives of both the 'splitting' and 'lumping' interests; and if the points at issue were fairly debated, with a full determination to give and take on both sides, it is difficult to believe that a working compromise between the extreme views could not be arranged. Almost anything is better than the present condition of uncertainty and discrepancy."

THE Plague Commission sent by the Austrian government to Bombay to study the disease has presented a provisional report to the Vienna Academy of Science. According to the *British Medical Journal* the Commissioners state that they had opportunities of investigating the plague clinically in 70 cases, and that they had opportunities of making pathological and bacteriological investigations on 47 bodies of persons who had died of the disease. Pathologically they say that three forms of plague can be distinguished: a septicæmic-hæmorrhagic

form, in which the whole lymphatic apparatus appears to be diseased in a peculiar manner; a septico-pyæmic form, with metastases to internal organs; and primary plague-pneumonia, a lobular pneumonia with quite characteristic appearances. The mode of entrance of the infection seems mostly to be the skin, more rarely the lungs and the tonsils, never the intestinal canal. The Yersin-Kitasato bacillus is certainly the exciting cause of the disease; it can be obtained pure from the organs as well as from the blood. The Commissioners were unable to satisfy themselves that Haffkine's serum injections had any effect. They considered it improbable that the plague could find a footing in Europe.

THE commission on the plague under the direction of Professor Koch has also issued its report. It states, according to the London *Times*, that the plague bacillus outside the human body or certain animals has very brief vitality. Pure cultures with which experiments were made were killed by sublimates at boiling temperature immediately, by mineral acids in five minutes, by a solution of 1 per cent. of carbolic acid in ten minutes, and by milk of lime exposed to sunlight in one hour. The duration of the life of the bacillus was found to be from eight to ten days at the most. Rats were found to be in the highest degree susceptible and to be spreading the plague germs and communicating them to human beings. For experiments on immunity Yersin serum was used with apes. Its protective power in the case of brown apes did not exceed eight days. Strong injections of serum proved to be of unquestionable curative efficacy. Haffkine's system of inoculation, which was applied to 1,400 patients, is said, contrary to the report of the Austrian Commission quoted above, to have showed undoubted protective results, although a number of the patients were taken ill in consequence of the inoculation.

REGULATIONS have been issued by the German government for the sale of Professor Koch's new tuberculin, under which name the new specific will be sold by chemists in phials containing one millilitre at Marks 8.50 and in phials containing five millilitres at Marks 42.50. The tuberculin will only be given to certified medical men or to those provided with an authorization from such.

A RESOLUTION has been submitted to the municipal council of Paris requiring families to furnish every two months a medical certificate stating that infants under one year have been cared for in accordance with hygienic rules.

UNIVERSITY AND EDUCATIONAL NEWS.

THE full text of the government bill with respect to the University of London is published in the issue of the *Times* for July 24th. The Commissioners are Lord Davey, Dr. Mandell, Lord Bishop of London, Lord Lister, Sir William Roberts, M.D., Sir Owen Roberts, Professor Jebb and Mr. E. H. Busk. The Commissioners are required to make statutes and regulations for the University of London in general accordance with the recommendations of the Cowper Commission. The Commissioners are to be superseded at the end of 1898 by a Senate of the University consisting of the Chancellor and other representative members. The Senate has entire conduct of the University, it only being provided that:

(*a*) No religious test shall be adopted, and no applicant for a University appointment shall be at any disadvantage on the ground of religious opinions;

(*b*) No procedure to a higher degree shall be allowed without examination or other adequate test, nor shall any honorary or *ad eundem* degree be conferred unless the Senate, in exceptional cases, think fit to confer such a degree on a teacher of the University;

(*c*) No disability shall be imposed on the ground of sex.

A LAW passed by the last Legislature of the State of Illinois appropriated to the State University the sum of $456,000, lost to the University by the defalcation of the former Treasurer.

THE faculty of sciences of the University of Paris has been authorized to give a certificate for higher studies in physical geography.

A NEW technical school at Northwich, built by Sir Joseph Verdin at a cost of £12,000, was formerly opened on July 24th.

IT is proposed to establish at Shanghai a university for the education of the Chinese in Western art, science and literature.

DR. R. S. CURTIS, of the University of Chicago, has been elected professor of chemistry in Hobart College.

MR. JOHN P. HYLAN has been appointed instructor in experimental psychology in the University of Illinois.

DR. HOPE, lecturer on hygiene at University College, Liverpool, has been made professor.

DR. TRAUBE, Privatdocent at Berlin, has been appointed to the newly established professorship in the Technological Institute at Charlottenburg, and Dr. Adalbert Kolb, Privatdocent in chemistry in the Technological Institute at Darmstadt, has been promoted to a professorship.

DISCUSSION AND CORRESPONDENCE.

CEREBRAL LIGHT.

IN SCIENCE for July 23d, p. 138, I find a letter from Dr. Scripture in which he makes some very acute observations on the the origin of the figures, usually irregular and obscure, but sometimes quite definite, which are seen in the dark field of the closed eyes. In past years I have spent many hours in studying these figures and they are briefly described in my little volume on Sight, pp. 66 and 67 of last edition. They are usually considered as of retinal origin and sometimes spoken of as 'retinal light;' but Dr. Scripture gives what he thinks conclusive reasons for thinking that they are of cerebral origin, and therefore proposes the name 'cerebral light.' Now, as to the question of origin, I am not prepared to say anything. I wish now only to show that his supposed tests are not valid.

1. He says that with the eyes closed there is but *one* dark field, instead of two, as there ought to be if its origin is retinal; for there are two retinæ. Now, if he means the simple field without reference to the figures in it, I would ask: How could there be more than one? Even with the eyes open, there seems to be but one field. Only by close observation can we see that there are really two partly overlapping fields forming a common field bounded on the two sides by the faint images of the nose. But in the dark field there are no images of the nose. But if, on the other hand, he means that the two retinæ could not be expected to be similarly affected in all parts, and therefore there ought to be different figures for the two retinæ in the same dark field, then I would ask again: How are we to distinguish the figures belonging to each retina in the one dark field?

2. But, in further proof, he says: These figures do *not move* with the movements of the eye; while after-images, which are admittedly retinal affections, do thus move. Now, I find, on the contrary, that these figures behave exactly as the after-images do. I find that, in looking in a different direction in the dark field, they may indeed disappear, but only to reappear at the new point of sight. After-images do the same. Unless they are very strong, they also, on changing the point of sight, disappear to reappear at the new point.

It is possible, however, that we are talking about different things. It is possible that there are two different kinds of figures in the dark field, one retinal and the other cerebral.

3. But, again, he says that these figures do not change place when the axis of the eye is displaced by pressure in the corner, whereas after-images do change place under these conditions. Now, on the contrary, I find that after-images under these conditions do *not* change place. It is true that with the eyes open they may *seem* to move, but this is only an illusion, the result of the contrary motion of all objects in the field of view. Real objects move because their images change their places on the retina while we look in the same direction, but the retinal brands which cause after-images cannot change their places on the retina. But now shut the eyes, so that there are no objects to plague us; then we find that after-images do not move by displacement of the axis of the eyes. There is only one case (that of the previous head) in which after-images follow the motions of the eye, although it is the commonest case. It is that in which the two eyes move together in the same direction. In other words, they follow the direction of looking, not the direction of the individual eye. But in displacement of the eye-axis by pressure we do not change the direction of the *looking* of the observer.

A convenient method of proving the above is as follows: Darken the experimental room slightly by closing the windows, but leave a crack between the shutters, showing a strip of bright sky. Now gaze with *one* eye, say the right, on the crack until its image is branded on the retina. If we now turn about and look at the wall in various directions the after-image, of course, follows all the motions of the eye. Even if we shut the eye and look about the field of darkness the after-image follows all the motions of the eye. But if, with eyes still shut and looking straight in front, without changing the direction of looking, we press in the external corner of the branded eye the after-image does not move. It still remains directly in front.

We have given this experiment as most convenient, but we may use a retinal brand produced by the setting sun with still more conspicuous results.

One more experiment to show the behavior of after-images in the movements of the eye. Gaze with *both* eyes on the crack of the previous experiment, until its image is strongly banded on the vertical meridian of both retinæ. On turning about and looking at the wall the after-image is distinctly seen and follows with exactness all the motions of the eyes in looking about. But now *converge* the eyes until they look at the root of the nose. Of course, each eye changes its direction at least forty-five degrees, but the direction of the after-image does not change. It is still directly in front. The reason is that, while each eye *individually* changes its direction, the binocular observer looks in the same direction, though at a nearer point. The two external images of the retinal brands cannot separate, as the images of an object do, because the brands are on corresponding points and have the same spatial representative and, therefore, must be seen single. This is the reason, as I have fully explained in my volume 'Sight,' pp. 199 and 200, why after-images cannot be used to test the motions of the eyes by rotation on the optic axis in *convergence*, although they are such accurate tests in *parallel motion*.

JOSEPH LE CONTE.

BERKELEY, CAL., July 29, 1897.

SCIENTIFIC LITERATURE.

Leitfaden der Praktischen Physik, mit einem Anhange, Das absolute Maas-system. VON F. KOHLRAUSCH. Achte Auflage, B. G. Teubner, Leipzig.

Each new edition of this book has been characterized by such considerable additions that the modest guide to elementary laboratory work in physics, which first appeared under this title more than twenty-five years ago, has become a reference volume of some five hundred pages, as valuable to the advanced worker as to the beginner.

A laboratory manual should cover the entire field without undue specialization in any one direction, and without any omissions. Kohlrausch's book does this for physics more satisfactorily than any other. In fact, the manuals edited in America are too evidently, and often avowedly, nothing more than a compilation from the course given at the particular institution at which the author is teaching, and hence possess all the peculiarities and limitations of the work at that laboratory, and too often are of slight value elsewhere, with different conditions and facilities.

Kohlrausch sets forth not what is done at Würzburg or Strasburg, or even at Berlin, but what ought to be done under ideal conditions in a complete laboratory. The book is a guide to the instructor as to what experiments should be performed, as well as to the student as to how they are to be performed.

As regards the explanation of the operations, the author seems to have followed most successfully the principle laid down in the preface to this edition, "to carry the scheme, the explanation, and the setting-up of the apparatus for an experiment no further than is rendered necessary for the successful operation of a laboratory attended by a large number of students." He has achieved the happy mean between allowing the pupil to flounder too long in the working out of an experiment, and giving him such minute instructions that the necessity for originality of thought on his part is entirely eliminated.

It is difficult to select parts of this book as worthy of special mention, and yet certain subjects are treated in a manner in especially

agreeable contrast to that found in similar manuals. The calculation of corrections and the discussion of the effect of the errors of observation upon the result, as well as the methods of least squares and of approximation, will be found particularly clear, complete and useful. Indeed, much of the unique value of the book lies in its many suggestions as to simple manipulative methods, receipts and general good advice. It is these little 'tricks of the trade' that distinguish the successful experimental investigator from the helpless theorizer.

The body of the book contains concise, clear instructions for the determination of about every quantity that may be of interest to the experimental physicist, together with numerous demonstrations and illustrative examples. An excellent feature of this part is the frequent reference to the original investigations from which the methods were derived.

The absolute system of units is happily not the novelty to-day that it was when Kohlrausch introduced it into the Leitfaden; nevertheless his clear and complete exposition of its principles, its units and their values is very acceptable even now, and gives in some twenty pages the essentials of the whole matter.

The thirty pages of carefully selected tables form a very agreeable and striking contrast to some similar books recently offered in this country.

Some teachers have lamented the absence of pictures of instruments, but it would appear inconsistent with the general nature of the book if specific pieces of apparatus were represented. It is better and probably easier for a pupil to specialize from a diagram to any corresponding instrument than from one instrument to another of radically different appearance, though similar in principle.

The English translation of the last edition of Kohlrausch is very good, but not so good as the original because the translator has permitted himself to make changes.

A Systematic Treatise on Electrical Measurements. By HERSCHEL C. PARKER. Spon & Chamberlain, London and New York.

Mr. Parker, confining himself to a smaller field, and rather to the technical than the theoretical aspect of the subject, has succeeded in following the good example of Kohlrausch and sets forth what such a course should teach, rather than what is taught under the conditions at Columbia.

Particularly valuable is the strictly systematic way in which the subject is treated, enabling the student to see at a glance the relative merits of different instruments and methods for the various measurements of the same class, and to choose the apparatus and method best adapted to his particular determination. Although giving the principle and construction of the latest forms of electrical measuring instruments, the author has done better than some others, who could not resist the temptation to use old cuts or introduce trade pictures of apparatus. His diagrams and outline cuts show the fundamental parts most satisfactorily and enable the reader easily to imagine the brass and hard-rubber accompaniments. The book is sure to be useful to the electrical engineer, as well as to the investigator, who will gladly welcome future editions with the revision and additions which the author seems to feel desirable.

WILLIAM HALLOCK.

Bibliography—A Study of Resources. CHARLES SEDGWICK MINOT. In *Biological Lectures delivered at the Marine Biological Laboratory of Wood's Holl in the summer session of 1895.* Boston, Ginn & Company. 1896. P. 149–168.

Short surveys of the present standpoint of bibliography from the point of view of the special sciences should prove advantageous both for the specialist and for the bibliographer. To the former such surveys would be mainly useful in giving him a systematic guide through the mass of publications which he must work over to find the particular literature needed for his investigations. To the latter—I am here thinking especially of the librarian—they would make plain the connection of bibliography with the special sciences of which bibliography is the handmaid. Professor Minot's account of biological bibliographical literature is a good example of what such a survey should be. He does not drown his subject in enumeration of details, but describes and considers the main

guides to biological literature. One could wish to have as an appendix to the lecture a list, with full bibliographical details, of the publications treated, showing especially the connection and succession of the numerous German *Jahresberichte* and *Anzeiger*. As it is, however, the lecture makes not only an admirable introduction to biological bibliography, but also very interesting reading. The bulk of the lecture is devoted to the bibliographical publications in question, which are divided into four classes: (1) Standard bibliographies; (3) Incidental bibliographies; (3: a.) Current bibliographies appearing annually; (3: b.) Current bibliographies appearing at intervals of less than a year. As an introduction Professor Minot gives an interesting account of his own methods of dealing bibliographically with his literary material and with his library. In connection herewith he also gives some few rules for dealing with a scientific subject from the point of view of the bibliographer, emphasizing that the *title* of an article 'should be as brief as possible and nevertheless indicate the contents;' that *a table of contents* should be used in longer articles, say of 40 to 100 pages; that *reprints* should have the paging of the original publications; and that *references to other authorities* should be carefully arranged.

AKSEL G. S. JOSEPHSON.

THE JOHN CRERAR LIBRARY, CHICAGO.

Indiana—A Century of Changes in the Aspects of Nature. A. W. BUTLER. President's Address. From Proceedings Indiana Academy of Sciences, No. V., 1895.

This pamphlet of a dozen pages gives an interesting account of the changes in the natural conditions in Indiana, brought about by the advent of the white man, the passing away of the virgin forests, the destruction of the herds of buffaloes, the elk, the flocks of wild turkeys, the pigeons and many more.

In the valleys of the Wabash and Whitewater there were magnificent forests of deciduous trees, which probably could not be surpassed anywhere in America. Forty-two trees in the Wabash valley attained a height above one hundred feet, the tallest recorded being a tulip poplar (*Liriodendron tulipifera L.*), 190 feet high. The bison or buffaloes had well marked roadways in some of the river valleys, along which countless thousands passed annually, chiefly on their journey to and from the Big Bone Lick, in Kentucky. Elk and deer were common, bear and wolves quite abundant, beaver were found in many localities, while the wild cat Canada porcupine and panther were numerous. Wild turkeys and pigeons and the beautiful little Carolina paroquets were more than abundant, but have been almost, or in a great measure, exterminated. The hog assisted in the killing of the rattlesnakes and copperheads.

Thus, with the aid of the gun, of fire and the axe, was the land, all things being considered, speedily made ready for the plow, and a new life of sparrows, of little snakes, humble bees and grasshoppers took possession of the fields. More than half of humanity will declare that the destruction was unavoidable and even commendable, but we trace a spirit of regret running through all of Mr. Butler's admirable address, and this speaks for the rest of mankind, who would fain have saved a tract of virgin forest where they might resort to contemplate some of the wonders of the world.

ALFRED MARSHALL MAYER.

A man of science, whose work was unique in the domain which he had selected, and who will long be held in warm remembrance by a large circle of friends, has lately passed away.

In 1784 there emigrated to America a young German, Christian Mayer, a member of an ancient family in the city of Ulm, in Würtemberg. He made his home in Baltimore, where, by strong intelligence and well directed industry, he amassed a fortune. To his two sons, Charles F. and Brantz, he gave the best educational advantages of the day. The former became a prominent lawyer, well known in the best social circles of Baltimore on account of his refinement and broad literary culture, while the latter traveled and wrote extensively, his historical work, especially in connection with Mexico, being of high authority and acknowledged value.

On the thirteenth day of November, 1836, a son was born to Charles F. Mayer. At an early age the boy exhibited great mechanical ingenuity and a lively interest in the external world of nature. At St. Mary's College, in Baltimore, he was afforded all the usual facilities for an elementary liberal education, and especially for classical training; but this did not suit his native bent. At the age of sixteen years he gave up the school room, and the following two years were spent chiefly in the workshop and the draughting room of a mechanical engineer. Here was abundant opportunity for acquiring familiarity with the use of tools and developing manipulative skill. At the same time there was a continual stimulus to private study in connection with the daily application of the laws of physics and mechanics. This course of study in applied science was a natural precursor to the resumption of more systematic work, not in the class room, but in the laboratory. A course of

chemistry was undertaken, and two years were spent largely in mastering the principles and processes of quantitative analysis.

It was during these years of private study and practical work that young Mayer attracted the attention of a man whose personal influence was chiefly instrumental in determining the future direction of the student's energies. Joseph Henry was at this time Secretary of the Smithsonian Institution, and for thirty years he had been identified with the advancement of pure science in America. Industrial science needs no advocates. Its importance is recognized by all. Its immediate connection with material progress and its quick response to commercial demands are sufficient to bring within the ranks of its devotees the great majority of those who undertake laboratory work with a definite purpose. Henry had never underrated the value or the need of industrial science, but he had emphasized the importance of investigation from the more unselfish standpoint of one who regarded intellectual acquisition as a priceless good in itself apart from all commercial recompense. He apprehended the brightness, the alertness, the originality of the Baltimore student, and accorded him that sympathetic recognition which constitutes the greatest stimulus that a young man can receive. The friendship of an acknowledged master makes a willing and easily directed pupil. Ideals of excellence are thus formed for life. Subsequent experience may sometimes modify these, but they are rarely ever discarded.

At the early age of twenty years Mayer was appointed to the chair of physics and chemistry in the University of Maryland. He had already during the previous year published his first contribution to science, the description of a 'new apparatus for the determination of carbonic acid.' This was soon republished in Germany. His new duties absorbed now most of his time, but a second paper appeared in the *American Journal of Science*, in 1857, on the estimation of the weights of very small portions of matter. In this he showed that by the deflection of a fine glass fibre it is possible to estimate a variation in weight so small as the thousandth part of a milligram. In 1859 he accepted a chair in Westminster College, Missouri, where two years were spent; but the equipment of this institution was insignificant and no original work was accomplished. The breaking out of the Civil War determined his return to Baltimore, and in 1863 he went to Paris, where two years were occupied in special study, chiefly under the direction of Regnault. The influence of the great French physicist, and the general atmosphere of the University of Paris, strengthened the bias in favor of pure science which had been received in youth from Henry.

Soon after his return to America, in 1865, Professor Mayer was called to the chair of physics and chemistry at Pennsylvania College, in Gettysburg, which he gave up, in 1867, to accept that of physics and astronomy in Lehigh University. This in turn was renounced in 1871 for the purpose of joining in the upbuilding of the new Stevens Institute of Technology, at Hoboken, with which his connection continued up to the time of his death, July 13, 1897. It is with this institution, therefore, that his name will always be chiefly identified, though his researches were for the most part in channels somewhat removed from those that are usually characteristic of an engineering school. Its instrumental equipment was unusually good, and proximity to a great metropolis afforded the intellectual stimulus and the prompt recognition of merit which are wanting in isolated institutions of learning.

While connected with Lehigh University,

Professor Mayer designed an astronomical observatory and superintended its construction. He erected the instruments and, without assistance, finished the tedious work of adjusting them. A series of observations on Jupiter followed, and its publication was reproduced in England. During the summer vacation of 1869 he was deputed by the United States government to take charge of a party of astronomers at Burlington, Iowa, where the solar eclipse of August 7th was observed. During the eclipse more than forty successful photographs were taken, each exposure lasting 0.002 second. Four of these were during the eighty-three seconds of totality. This was in the early days of instantaneous photography and was accounted an unusual feat. An abstract of the results of measurements on these photographs was published in the Journal of the Franklin Institute. In the same journal, about this time, he published a number of articles on physical and astrophysical subjects. At the Salem meeting of the Scientific Association, 1869, a paper was read 'On the thermodynamics of waterfalls.' At Trenton Falls and at Niagara Falls careful observations had been made on the temperature of the water at the top of the cataract and just beyond the point of impact at the bottom. The arrest of motion develops heat, and this was found to be manifested in a measurable rise of temperature, when the air was charged with moisture and not much warmer or colder than the water, the change being in accordance with calculation based on Joule's equivalent. But under other conditions this effect was masked to such an extent by the cooling effect of evaporation and conduction that there was sometimes a lower temperature at the bottom than at the top.

Soon after entering upon his duties at Hoboken, Professor Mayer began the series of investigations in acoustics for which he is perhaps best known, and which made him decidedly the leading authority on this subject in America. In the first of his papers he showed how the co-vibration of two nearly unisonant tuning forks may be utilized to demonstrate Doppler's well-known principle that wave-length may be modified by translation of the vibrating body. This was soon followed by another paper in which he gave a method of detecting the phases of vibration in the air surrounding a sounding body. Two resonators responding to the pitch of the source were employed, each connected with a manometric capsule. One of these resonators being fixed and the other movable, the recurring changes in the compound flame image gave the means of measuring wave-lengths directly in the vibrating air and exploring the form of the wave surface. A simple and precise method was developed from this for measuring wave-lengths and velocities of sound in gases at various temperatures; and an acoustic pyrometer was devised by which furnace temperatures were capable of measurement with a degree of accuracy approaching that of the air thermometer. The same optical method of interference was then further applied to the determination of the relative intensities of sounds. The range of application of this method is somewhat limited, but within this range it is more precise than any other method devised for the same purpose. One application was to the measurement of the powers of various substances to transmit and to reflect sonorous vibrations. An investigation of the relative absorbing powers of different media for sound led to an approximate determination of the mechanical equivalent of an aërial sonorous vibration. The energy per second given forth in aërial vibrations by an Ut_3 fork (256 vd.), set in motion by intermittent electro-magnetic action and placed before an appropriate resonator, was

found to be about one millionth of Joule's unit, or enough to raise one gram through a height of ten centimeters. This result was accomplished by measuring the relative intensities of the sound given forth by the same fork, first when vibrating freely, then when the motion of its prongs was damped by the expenditure of part of its energy on india rubber. The rise of temperature of the rubber was measured by use of thermopile and galvanometer, and its specific heat determined by ordinary methods. The difficulties attendant upon such an experiment are very great, and no one but an experimentalist of exceptional skill and patience would be apt to undertake it.

These strictly physical investigations led Professor Mayer into the domain of physiology in its bearing upon the phenomena of audition. The most important principle in acoustics is that of harmonic motion, simple and compound, as embodied in Fourier's theorem. Helmholtz was the first to apply this to the analysis of musical quality, and in doing so the subjective method of resonators was utilized with great skill. Professor Mayer sought objective methods and devised several of these, the most striking of which was that of employing tense threads as media for the conveyance of energy from a vibrating membrane to mounted tuning forks adjusted in pitch to respond to the components of the compound sound under examination. Recognizing the capacity of the ear, when sufficiently trained, to accomplish this analysis to a considerable extent without instrumental aid, he sought to learn the mechanism of the auditory apparatus of some of the lower types of animal life. Some new and interesting facts were thus discovered in relation to the function of the antennæ of the mosquito in audition, and he showed how an insect may determine the direction of sounds by means of its antennæ. In this connection good reason was found for the belief that the terminal auditory nerve fibrils in the human ear vibrate just half as often in a given time as the membrane of the tympanum and the ossicles. This hypothesis partially accounts for the marked difference in quality when the same sound is successively heard, first directly through the open ear and then through the medium of the bony portions of the head.

Professor Mayer's most important acoustic research was his determination of the law connecting the pitch of a sound with the duration of the residual sensation in the ear. An explanation of the method adopted cannot be here given without entering unduly into details. This law gave a quantitative character to results which Helmholtz had attained only qualitatively. It is of fundamental importance in its application to musical harmony. It explains why certain combinations of tones which are harmonious in the upper portions of the musical scale become rough and discordant in the lower portions. This mere fact the musical composer was long compelled to recognize, though hitherto it had been inexplicable. The labor involved in this work was great, and before its completion the investigator's power of audition in one ear was thereby permanently impaired. The first experiments were published in 1874; a redetermination was made in 1875, and again with improved apparatus in 1893. He received the assistance of the most accomplished musical experts, including Madame Seiler, who had been associated with Helmholtz for a somewhat similar purpose, and Dr. Rudolph Koenig, of Paris, whose training in the detection of musical beats is unrivaled. Dr. Koenig, in 1893, rendered important service in ascertaining the limitations of what may now be properly called 'Mayer's Law.' This law is expressed by an equation in which the duration of the residual sensation is given as a function of vibration frequency, and

this equation is readily translated into a curve. Between the limits of 100 and 4,000 vibrations per second there is closer accordance between the results of calculation and observation than in the case of Fechner's law, or indeed any other physiological law for which the attempt has been made to express sensation mathematically. Between 200 and 2,000 vibrations, including the range most constantly resorted to in music, the accordance is satisfactory, even when measured by physical rather than physiological standards. Due recognition of these important contributions to acoustic theory have been made by Mr. Ellis in his translation of Helmholtz's 'Tonempfindungen,' and by Professor Zahm in his recent book (1892) on 'Sound and Music.' Mr. Ellis gave a special lecture in London for the purpose of explaining these discoveries and their application to the principles of musical harmony.

It was natural for Professor Mayer to apply acoustic methods in work primarily undertaken for other purposes. In 1876 he devised improvements in what is now generally known as the electrographic method for the measurement of the velocity of projectiles and the determination of pitch. He utilized the spark from an induction coil for the purpose of marking seconds upon the sinuous trace of a tuning fork on smoked paper, and attained results of great accuracy. He studied with care the laws of vibration of tuning forks, and was the first to give accurately the correction to be applied in all such determinations on account of variation in temperature of the fork. Between 1889 and 1894 he conducted an elaborate research on the variation of the modulus of elasticity of various materials with change of temperature, as indicated by the transverse vibration of bars. From the observed pitch the velocity of propagation of sound in the bar is found, and this gives the modulus of elasticity. For the accurate determination of pitch it was necessary to visit Paris, where access was had to Dr. Koenig's grand tonometer, and where this accomplished acoustician freely gave his time and skill in furtherance of the work. The remarkable regularity in the results shows that this acoustic method, as conducted, is worthy of the greatest reliance. Among the materials thus studied was aluminum. Its modulus was found to be subject to large variation, and in every respect it is far inferior to steel for acoustic purposes.

Among the acoustic discoveries of Professor Mayer may be mentioned his observation that the sensation of a sound may be obliterated by the simultaneous action on the ear of another sound of greater volume and lower pitch, but that the converse is not true. The higher pitch, even when intense, cannot obliterate the sensation of another sound of lower pitch. This does not imply that the higher pitch is thus always completely obliterated. Its presence modifies the compound perception after the possibility of singling it out has vanished. The apprehension of this truth caused him to suggest certain changes in the method of conducting orchestral music, but they were not adopted on account of counter-balancing inconveniences in practice.

In 1876 Professor Mayer discovered that the air pressure on the inner surface of the bottom of a resonator in action exceeds that on the corresponding outer surface. This led to the construction of the 'sound mill,' composed of pairs of resonators so balanced and pivoted on their supports as to be set into rotation by reaction on sounding near them a tuning fork to which they are adapted. This phenomenon of acoustic repulsion was shortly afterward discovered independently by Dvorâk in Austria. Another application of resonators by Professor Mayer was in the invention of the topophone, an instrument with which the direc-

tion of sound at sea, such as that of a fog horn, could be determined with a close approximation to accuracy. His last publication in acoustics was on the production of audible beat tones from two vibrating bodies whose frequencies are so high that the separate tones are inaudible. This paper was read at the Oxford meeting of the British Association in 1894. The existence of such beat tones has been doubted by some. In the present case I was associated with Professor Mayer during some of his experiments, and had previously had considerable experience in the use of the sources of sound which he employed. As to the reality of the results he claimed there cannot be the least doubt on the part of any person possessing ordinarily acute powers of hearing, who will take the trouble to repeat the experiments.

The study of the physiology of sensation tempts to the investigation of the problems of vision in connection with those of audition. During the winter and spring of 1893 Professor Mayer became much interested in the phenomena of simultaneous color contrast, of which it may yet be said that no satisfactory explanation is provided by any existing theory of color vision. It has been common to assume that the modification of color perception induced by contrast is due to unconscious motion of the observer's eyes, to error or fluctuation of judgment, or to incipient retinal fatigue. Professor Mayer devised a variety of methods of presenting these phenomena with unexampled vividness, and on so large a scale as to enable him to arrive at quantitative statements of such subjective color by comparison with standard hues with which they were matched on the revolving color disk. Vivid contrast hues were readily perceptible when the illumination was secured by means of a momentary electric flash, and with entire accordance between different observers who had been purposely misled to expect something different from what they actually perceived. The hypothesis of retinal fatigue, or fluctuation of judgment, or ocular motion, is excluded under such conditions. This psychological element of color contrast led to the development of a disk photometer for measurement of the brightness of colored surfaces. In the use of it a degree of accuracy was attained in excess of that usually found possible with the Bunsen photometer.

While still at the Lehigh University Professor Mayer began investigations on electricity, on magnetism and on heat, which were resumed from time to time during subsequent years in the intervals between his acoustic researches. His lecture notes on physics were published serially in the Journal of the Franklin Institute, and, subsequently, put into book form. He devised a zero-method of comparing the strengths of electro-magnets and electrical conductivities, made many observations on magnetic declination, and improved on previously known methods of fixing and photographing magnetic spectra. He undertook an elaborate research on the effect of magnetization in changing the dimensions of iron and steel bars, an effect discovered by Page in 1837, investigated by Joule in 1842, and then neglected for thirty years. It was about this time that an unusually large electro-magnet was constructed for the Stevens Institute of Technology, and was employed with much effect in public lectures. One of these, entitled 'The Earth a Great Magnet,' was given by invitation of the Yale Scientific Club and, subsequently, published. In connection with it a special form of lantern galvanometer was devised for vertical projection, which attracted much notice. Another lecture demonstration which a few years afterward attracted general attention was that of the configurations formed by magnets floating vertically and subjected to the attraction of a superposed magnet.

The multiple or oscillatory character of the electric discharge from a Leyden jar was discovered by Henry in 1842. It was carefully studied afterward by Feddersen, who used a revolving mirror, and yet more fully by Rood, who employed several methods, but more particularly that of the revolving disk with radial slits. Professor Mayer, in 1874, took advantage of centrifugal action to give steadiness to a disk of blackened paper rotated rapidly between the electrodes employed for transmission of the spark. The perforations were then subjected at leisure to micrometric measurement. Since the rotation of the disk is known, the means is thus afforded for measuring the duration of the discharge and the intervals between the successive sparks which compose it. The conditions were then studied for securing the most nearly simple discharge possible. This served as the necessary antecedent to the successful employment of the induction coil in conjunction with a method previously devised for measuring minute intervals of time with the tuning fork, or rating a tuning fork by comparison with a standard clock. The combination formed an admirable chronoscope for a variety of purposes, but more especially for measuring the velocity of projectiles.

On the general subject of heat Professor Mayer published several articles. The first of these, in relation to waterfalls, has been already mentioned. In 1872 he devised a method of tracing the progress and determining the boundary of a wave of conducted heat by taking advantage of the variation in color with change of temperature which is characteristic of certain double iodides. The same method was applied three years afterward to the securing of thermographs of the isothermal lines of the solar disk. In 1890 he gave publication to a paper on the determination of the coefficient of cubic expansion of a solid from the observation of the temperature at which water in a vessel made of this solid has the same apparent volume as it has at 0° C., and on the coefficient of cubic expansion of a substance determined by means of a hydrometer made of it. The method was applied to several different substances, including brass and vulcanite. This led to a general investigation of the properties of vulcanite, which was published soon afterward. One of these properties is its remarkably large coefficient of expansion, exceeding that of mercury.

Soon after the publication of Röntgen's discovery of a new species of radiation Professor Mayer's interest in this was aroused, and in June, 1896, he published the outcome of his investigation of herapathite, which had been employed by him to test the possibility of polarizing the Röntgen rays. Formulæ were deduced for the transmissive powers of several substances for these rays, including tourmaline, herapathite, glass, aluminum and platinum.

Professor Mayer's last scientific work was an experimental investigation of the equilibrium of the forces acting in the flotation of discs and rings of metal, and an application of such rings to the determination of the measure of surface tension of liquids. The method was wholly new, and the agreement among results was remarkable. At best, it has been difficult in the past to secure reliable results in work of this kind, and the present work is fully equal, if not superior, to the best hitherto accomplished by Plateau and Quincke. It was done during the intervals between periods of acute physical suffering, and its appearance in the *American Journal of Science* for April of the present year preceded by only a few days the paralytic stroke which demonstrated that the investigator's life work was already ended.

In this brief sketch of Professor Mayer's labors but little has been said of his numerous happy devices for lecture demonstra-

tion. His restless ingenuity was ever ready for any demand, and his mechanical aptitude was so directed by a delicate æsthetic sense that he could never be satisfied with any objective proof which was not neat and simple, as well as adequate. A few of these he published from time to time. Among them may be mentioned methods of measuring the angle of inclination of the mirrors employed in Fresnel's interference experiments; of obtaining a permanent trace of the oscillation plane of the Foucault pendulum; of registering and exhibiting the vibration of rods; of deducing the fundamental laws of electric repulsion by means of the pendulum; of measuring potentials and specific inductive capacities with the spring balance electrometer; of proving Ohm's law, and of expressing electric potential as work. Many of his demonstrations in acoustics were gathered into a small volume on 'Sound,' and have thence been copied into the elementary text-books of to-day. The same may be said of a little volume on 'Light,' prepared with the cooperation of Mr. Charles Barnard. In the student laboratory he was as efficient as in the lecture room, fertile in devices and ever insistent upon a high standard of accuracy. No one knew better than he that demonstration and practice work are of insignificant value in comparison with investigation; but he kept always in mind the fact that, in America at least, the physical investigator is nearly always compelled to be in some way a teacher, and that in teaching physical science demonstration and theoretic instruction must go hand in hand. He was conscious of his skill and, naturally, took keen pleasure in exercising it successfully. That in so doing he gave pleasure and help to others is manifested by the extent to which his methods have served as models.

The manipulative skill and tactile delicacy which are so necessary as adjuncts to independence and ingenuity in the laboratory were applied with no less success by Professor Mayer in out-door recreation. Early in life he became an accomplished marksman; and during manhood, as long as good health lasted, he was an ardent and exceptionally successful sportsman. His field and laboratory interests were combined in his application of the tuning fork to the problems of gunnery. In the *Century Magazine* he published a number of articles on sporting subjects. These were incorporated, along with contributions from other sources, in a volume entitled 'Sport with Rod and Gun in American Woods and Waters.' This volume was edited by Professor Mayer, and for it he specially prepared two valuable articles, one on 'The Shot Gun,' and another on 'The Blow Gun.'

In addition to these literary labors, Professor Mayer contributed many articles to the Cyclopedias of Appleton and Johnson, besides occasional popular articles on scientific subjects for other media of publication. In acknowledgment of his earlier contributions to science the degree of Doctor of Philosophy was accorded him in 1866 by Pennsylvania College. He was admitted to membership in the National Academy of Sciences in 1872, and was a member of each of the leading scientific societies of America, besides being a corresponding member of the British Association. He served during one year, 1873, as an associate editor of the *American Journal of Science*, and during the first eight months of that year five articles from his pen appeared in its pages. The partial failure of his eyesight then necessitated cessation from all work, and a considerable part of the next scholastic year was spent in England, where his reputation had preceded him and where hospitable entertainment was accorded by the most prominent representatives of science.

In the closer circle of personal friendship it is hard to speak with impartiality while the sense of bereavement is still fresh. A man's personality penetrates into all that he does, into his writings quite as unmistakably, if less positively, than into his conversation and the atmosphere of his home. In a eulogy on Joseph Henry, to which I listened at Cambridge just seventeen years ago, Professor Mayer said: "His best eulogy is an account of his discoveries; for a man of science, as such, lives in what he has done, and not in what he has said, nor will he be remembered for what he has proposed to do." In comparing Henry with Faraday he remarked: "Each loved science more than money, and his Creator more than either." Mayer proved himself a worthy pupil of Henry, and their friendship grew in strength until broken by the last great Destroyer. His words may now be properly applied to himself. The characteristics of the gentleman, the high-toned man of honor, were born in him. They needed no cultivation beyond the natural development and confirmation which accompany the attainment of maturity. Those who were favored with his friendship need no reminder of his generosity, his ready sympathy, his quick insight and hearty appreciation, his enthusiasm verging sometimes almost upon that of boyhood.

The value of Mayer's work will be tested by time. For some parts of it he will unquestionably be long referred to as an authority by stranger as well as friend. He dwelt in an atmosphere essentially unfavorable to the spirit which directed his work, for nowhere in the world can there be found so high a degree of general civilization conjoined with so small a degree of general appreciation of pure science as in America. This may be said with full recognition of the abundant rewards here accorded to science successfully applied in industrial fields, and of the rich endowments given by wealthy individuals to some of our educational institutions. But the man who advances theoretical science in America receives not a tithe of the recognition given to the inventor who puts on the market a merchantable device which pleases the multitude. Professor Mayer would have done his scientific work to better advantage in France or Germany. But be this as it may, we who knew him in his work must now know him only in memory. To have had him as a co-worker and friend is now a sad pleasure, and one that nothing can take away.

W. LeConte Stevens.

---

*ADDRESS OF THE PRESIDENT OF THE BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.**

Once more has the Dominion of Canada invited the British Association for the Advancement of Science to hold one of the annual meetings of its members within the Canadian territory, and for a second time has the Association had the honor and pleasure of accepting the proffered hospitality.

In doing so the Association has felt that, if by any possibility the scientific welfare of a locality is promoted by its being the scene of such a meeting, the claims should be fully recognized of those who, though not dwelling in the British Isles, are still inhabitants of that Greater Britain whose prosperity is so intimately connected with the fortunes of the Mother Country.

Here, especially, as loyal subjects of one beloved sovereign, the sixtieth year of whose beneficent reign has just been celebrated with equal rejoicing in all parts of her Empire; as speaking the same tongue, and as, in most instances, connected by the ties of one common parentage, we are bound together in all that can promote our common interests.

* Delivered by Sir John Evans at Toronto, August 18, 1897.

There is, in all probability, nothing that will tend more to advance those interests than the diffusion of science in all parts of the British Empire, and it is towards this end that the aspirations of the British Association are ever directed, even if in many instances the aim may not be attained.

We are, as already mentioned, indebted to Canada for previous hospitality, but we must also remember that, since the time when we last assembled on this side of the Atlantic, the Dominion has provided the Association with a President, Sir William Dawson, whose name is alike well-known in Britain and America, and whose reputation is indeed world-wide. We rejoice that we have still among us the pioneer of American geology, who, among other discoveries, first made us acquainted with the 'Air-breathers of the Coal,' the terrestrial, or, more properly, arboreal, Saurians of the New Brunswick and Nova Scotia coal-measures.

On our last visit to Canada, in 1884, our place of assembly was Montreal, a city which is justly proud of her McGill University; to-day we meet within the buildings of another of the universities of this vast Dominion, and in a city the absolute fitness of which for such a purpose must have been foreseen by the native Indian tribes when they gave to a small aggregation of huts upon this spot the name of Toronto—'the place of meetings.'

Our gathering this year presents a feature of entire novelty and extreme interest, inasmuch as the sister Association of the United States of America—still mourning the loss of her illustrious President, Professor Cope—and some other learned societies have made special arrangements to allow of their members coming here to join us. I need hardly say how welcome their presence is, nor how gladly we look forward to their taking part in our discussions and aiding us by interchange of thought. To such a meeting the term 'international' seems almost misapplied. It may rather be described as a family gathering, in which our relatives more or less distant in blood, but still intimately connected with us by language, literature and habits of thought, have spontaneously arranged to take part.

The domain of science is no doubt one in which the various nations of the civilized world meet upon equal terms, and for which no other passport is required than some evidence of having striven towards the advancement of natural knowledge. Here, on the frontier between the two great English-speaking nations of the world, who is there that does not inwardly feel that anything which conduces to an intimacy between the representatives of two countries, both of them actively engaged in the pursuit of science, may also, through such an intimacy, react on the affairs of daily life, and aid in preserving those cordial relations that have now for so many years existed between the great American Republic and the British Islands, with which her early foundations are indissolubly connected? The present year has witnessed an interchange of courtesies which has excited the warmest feelings of approbation on both sides of the Atlantic. I mean the return, to its proper custodians, of one of the most interesting of the relics of the Pilgrim Fathers, the Log of the 'Mayflower.' May this return, trifling in itself, be of happy augury as testifying to the feelings of mutual regard and esteem which animate the hearts both of the donors and of the recipients!

At our meeting in Montreal the President was an investigator who had already attained to a foremost place in the domains of physics and mathematics, Lord Rayleigh. In his address he dealt mainly with topics, such as Light, Heat, Sound

and Electricity, on which he is one of our principal authorities. His name and that of his fellow-worker, Professor Ramsay, are now and will in all future ages be associated with the discovery of the new element, Argon. Of the ingenious methods by which that discovery was made and the existence of Argon established, this is not the place to speak. One can only hope that the element will not always continue to justify its name by its inertness.

The claims of such a leader in physical science as Lord Rayleigh to occupy the Presidential chair are self-evident, but possibly those of his successor on this side of the Atlantic are not so immediately apparent. I cannot for a moment pretend to place myself on the same purely scientific level as my distinguished friend and for many years colleague, Lord Rayleigh, and my claims, such as they are, seem to me to rest on entirely different grounds.

Whatever little I may have indirectly been able to do in assisting to promote the advancement of science, my principal efforts have now for many years been directed towards attempting to forge those links in the history of the world, and especially of humanity, that connect the past with the present, and towards tracing that course of evolution which plays as important a part in the physical and moral development of man as it does in that of the animal and vegetable creation.

It appears to me, therefore, that my election to this important post may, in the main, be regarded as a recognition, by this Association, of the value of archæology as a science.

Leaving all personal considerations out of question, I gladly hail this recognition, which is, indeed, in full accordance with the attitude already for many years adopted by the Association towards anthropology, one of the most important branches of true archæology.

It is no doubt hard to define the exact limits which are to be assigned to archæology as a science and archæology as a branch of history and belles-lettres. A distinction is frequently drawn between science, on the one hand, and knowedge or learning, on the other; but translate the terms into Latin, and the distinction at once disappears. In illustration of this, I need only cite Bacon's great work on the 'Advancement of Learning,' which was, with his own aid, translated into Latin under the title '*De Augmentis Scientiarum.*'

It must, however, be acknowledged that a distinction does exist between archæology proper and what, for want of a better word, may be termed Antiquarianism. It may be interesting to know the internal arrangements of a Dominican convent in the Middle Ages; to distinguish between the different mouldings characteristic of the principal styles of Gothic architecture; to determine whether an English coin bearing the name of Henry was struck under Henry II., Richard, John or Henry III., or to decide whether some given edifice was erected in Roman, Saxon or Norman times. But the power to do this, though involving no small degree of detailed knowledge and some acquaintance with scientific methods, can hardly entitle its possessors to be enrolled among the votaries of science.

A familiarity with all the details of Greek and Roman mythology and culture must be regarded as a literary rather than a scientific qualification; and yet when among the records of classical times we come upon traces of manners and customs which have survived for generations, and which seem to throw some rays of light upon the dim past, when history and writing were unknown, we are, I think, approaching the boundaries of scientific archæology.

Every reader of Virgil knows that the Greeks were not merely orators, but that

with a pair of compasses they could describe the movements of the heavens and fix the rising of the stars; but when, by modern astronomy, we can determine the heliacal rising of some well-known star with which the worship in some given ancient temple is known to have been connected, and can fix its position on the horizon at some particular spot, say, three thousand years ago, and then find that the axis of the temple is directed exactly towards that spot, we have some trustworthy scientific evidence that the temple in question must have been erected at a date approximately 1100 years B. C. If on or close to the same site we find that more than one temple was erected, each having a different orientation, these variations, following, as they may fairly be presumed to do, the changing position of the rising of the dominant star, will also afford a guide as to the chronological order of the different foundations. The researches of Mr. Penrose seem to show that in certain Greek temples, of which the date of foundation is known from history, the actual orientation corresponds with that theoretically deduced from astronomical data.

Sir J. Norman Lockyer has shown that what holds good for Greek temples applies to many of far earlier date in Egypt, though up to the present time hardly a sufficient number of accurate observations have been made to justify us in foreseeing all the instructive results that may be expected to arise from astronomy coming to the aid of archæology.

The intimate connection of archæology with other sciences is in no case so evident as with respect to geology, for, when considering subjects such as those I shall presently discuss, it is almost impossible to say where the one science ends and the other begins.

By the application of geological methods many archæological questions relating even to subjects on the borders of the historical period have been satisfactorily solved. A careful examination of the limits of the area over which its smaller coins are found has led to the position of many an ancient Greek city being accurately ascertained; while in England it has only been by treating the coins of the ancient Britons, belonging to a period before the Roman occupation, as if they were actual fossils, that the territories under the dominion of the various kings and princes who struck them have been approximately determined. In arranging the chronological sequence of these coins, the evolution of their types—a process almost as remarkable, and certainly as well defined, as any to be found in nature—has served as an efficient guide. I may venture to add that the results obtained from the study of the morphology of this series of coins were published ten years before the appearance of Darwin's great work on the 'Origin of Species.'

When we come to the consideration of the relics of the early Iron and Bronze Ages the aid of chemistry has, of necessity, to be invoked. By its means we are able to determine whether the iron of a tool or weapon is of meteoritic or volcanic origin, or has been reduced from iron-ore, in which case considerable knowledge of metallurgy would be involved on the part of those who made it. With bronze antiquities the nature and extent of the alloys combined with the copper may throw light not only on their chronological position, but on the sources whence the copper, tin and other metals of which they consist were originally derived. I am not aware of there being sufficient differences in the analyses of the native copper, from different localities in the region in which we are assembled, for Canadian archæologists to fix the sources from which the metal was obtained which was used in the manufacture of the ancient tools and weapons of copper that are occa-

sionally discovered in this part of the globe.

Like chemistry, mineralogy and petrology may be called to the assistance of archæology in determining the nature and source of the rocks of which ancient stone implements are made; and, thanks to researches of the followers of those sciences, the old view that all such implements formed of jade and found in Europe must, of necessity, have been fashioned from material imported from Asia can no longer be maintained. In one respect the archæologist differs in opinion from the mineralogist, namely, as to the propriety of chipping off fragments from perfect and highly finished specimens for the purpose of submitting them to microscopic examination.

I have hitherto been speaking of the aid that other sciences can afford to archæology when dealing with questions that come almost, if not quite, within the fringe of history, and belong to times when the surface of our earth presented much the same configuration as regards the distribution of land and water, and hill and valley, as it does at present, and when, in all probability, the climate was much the same as it now is. When, however, we come to discuss that remote age in which we find the earliest traces that are at present known of man's appearance upon earth the aid of geology and paleontology becomes absolutely imperative.

The changes in the surface configuration and in the extent of the land, especially in a country like Britain, as well as the modifications of the fauna and flora since those days, have been such that the archæologist pure and simple is incompetent to deal with them, and he must either himself undertake the study of these other sciences or call experts in them to his assistance. The evidence that man had already appeared upon the earth is afforded by stone implements wrought by his hands, and it falls strictly within the province of the archæologist to judge whether given specimens were so wrought or not; it rests with the geologist to determine their stratigraphical or chronological position, while the paleontologist can pronounce upon the age and character of the associated fauna and flora.

If left to himself the archæologist seems too prone to build up theories founded upon form alone, irrespective of geological conditions. The geologist, unaccustomed to archæological details, may readily fail to see the difference between the results of the operations of nature and those of art, and may be liable to trace the effects of man's handiwork in the chipping, bruising and wearing which in all ages result from natural forces; but the united labors of the two, checked by those of the paleontologist, cannot do otherwise than lead towards sound conclusions.

It will, perhaps, be expected of me that I should on the present occasion bring under review the state of our present knowledge with regard to the antiquity of man; and probably no fitter place could be found for the discussion of such a topic than the adopted home of my venerated friend, the late Sir Daniel Wilson, who first introduced the word 'prehistoric' into the English language.

Some among us may be able to call to mind the excitement not only among men of science, but among the general public, when, in 1859, the discoveries of M. Boucher de Perthes and Dr. Rigollot in the gravels of the valley of the Somme, at Abbeville and Amiens, were confirmed by the investigations of the late Sir Joseph Prestwich, myself and others, and the co-existence of man with the extinct animals of the Quaternary fauna, such as the mammoth and woolly-haired rhinoceros, was first virtually established. It was at the same time pointed out that these relics belonged to a far earlier date than the ordinary stone weapons found

upon the surface, which usually showed signs of grinding or polishing, and that in fact there were two Stone Ages in Britain. To these the terms Neolithic and Paleolithic were subsequently applied by Sir John Lubbock.

The excitement was not less when, at the meeting of this Association at Aberdeen in the autumn of that year, Sir Charles Lyell, in the presence of the Prince Consort, called attention to the discoveries in the valley of the Somme, the site of which he had himself visited, and to the vast lapse of time indicated by the position of the implements in drift-deposits a hundred feet above the existing river.

The conclusions forced upon those who examined the facts on the spot did not receive immediate acceptance by all who were interested in geology and archæology, and fierce were the controversies on the subject that were carried on both in the newspapers and before various learned societies.

It is at the same time instructive and amusing to look back on the discussions of those days. While one class of objectors accounted for the configuration of the flint implements from the gravels by some unknown chemical agency, by the violent and continued gyratory action of water, by fracture resulting from pressure, by rapid cooling when hot or by rapid heating when cold, or even regarded them as aberrant forms of fossil fishes, there were others who, when compelled to acknowledge that the implements were the work of men's hands, attempted to impugn and set aside the evidence as to the circumstances under which they had been discovered. In doing this they adopted the view that the worked flints had either been introduced into the containing beds at a comparatively recent date, or if they actually formed constituent parts of the gravel then that this is a mere modern alluvium resulting from floods at no very remote period.

In the course of a few years the main stream of scientific thought left this controversy behind, though a tendency to cut down the lapse of time necessary for all the changes that have taken place in the configuration of the surface of the earth and in the character of its occupants since the time of the Paleolithic gravels, still survives in the inmost recesses of the hearts of not a few observers.

In his address to this Association at the Bath meeting of 1864, Sir Charles Lyell struck so true a note that I am tempted to reproduce the paragraph to which I refer:

"When speculations on the long series of events which occurred in the glacial and post-glacial periods are indulged in, the imagination is apt to take alarm at the immensity of the time required to interpret the monuments of these ages, all referable to the era of existing species. In order to abridge the number of centuries which would otherwise be indispensable, a disposition is shown by many to magnify the rate of change in prehistoric times by investing the causes which have modified the animate and inanimate world with extraordinary and excessive energy. It is related of a great Irish orator of our day that when he was about to contribute somewhat parsimoniously towards a public charity he was persuaded by a friend to make a more liberal donation. In doing so he apologized for his first apparent want of generosity by saying that his early life had been a constant struggle with scanty means, and that 'they who are born to affluence cannot easily imagine how long a time it takes to get the chill of poverty out of one's bones.' In like manner, we of the living generation, when called upon to make grants of thousands of centuries in order to explain the events of what is called the modern period, shrink naturally at first from making what seems so lavish an expenditure of past time. Throughout our early education we have

been accustomed to such strict economy in all that relates to the chronology of the earth and its inhabitants in remote ages, so fettered have we been by old traditional beliefs, that even when our reason is convinced, and we are persuaded that we ought to make more liberal grants of time to the geologist, we feel how hard it is to get the chill of poverty out of our bones."

Many, however, have at the present day got over this feeling, and of late years the general tendency of those engaged upon the question of the antiquity of the human race has been in the direction of seeking for evidence by which the existence of man upon the earth could be carried back to a date earlier than that of the Quaternary gravels.

There is little doubt that such evidence will eventually be forthcoming, but, judging from all probability, it is not in northern Europe that the cradle of the human race will eventually be discovered, but in some part of the world more favored by a tropical climate, where abundant means of subsistence could be procured, and where the necessity for warm clothing did not exist.

Before entering into speculations on this subject, or attempting to lay down the limits within which we may safely accept recent discoveries as firmly established, it will be well to glance at some of the cases in which implements are stated to have been found under circumstances which raise a presumption of the existence of man in pre-Glacial, Pliocene, or even Miocene times.

Flint implements of ordinary Paleolithic type have, for instance, been recorded as found in the eastern counties of England, in beds beneath the chalky boulder clay; but on careful examination the geological evidence has not, to my mind, proved satisfactory, nor has it, I believe, been generally accepted. Moreover, the archæological difficulty that man, at two such remote epochs as the pre-Glacial and the post-Glacial, even if the term Glacial be limited to the chalky boulder clay, should have manufactured implements so identical in character that they cannot be distinguished apart seems to have been entirely ignored.

Within the last few months we have had the report of worked flints having been discovered in the late Pliocene Forest Bed of Norfolk, but in that instance the signs of human workmanship upon the flints are by no means apparent to all observers.

But such an antiquity as that of the Forest Bed is as nothing when compared with that which would be implied by the discoveries of the work of men's hands in the Pliocene and Miocene beds of England, France, Italy and Portugal, which have been accepted by some geologists. There is one feature in these cases which has hardly received due attention, and that is the isolated character of the reputed discoveries. Had man, for instance, been present in Britain during the Crag Period, it would be strange, indeed, if the sole traces of his existence that he left were a perforated tooth of a large shark, the sawn rib of a manatee, and a beaming full face, carved on the shell of a pectunculus!

In an address to the Anthropological Section at the Leeds meeting of this Association in 1890 I dealt somewhat fully with these supposed discoveries of the remains of human art in beds of Tertiary date, and I need not here go further into the question. Suffice it to say that I see no reason why the verdict of 'not proven' at which I then arrived should be reversed.

In the case of a more recent discovery in Upper Burma, in beds at first pronounced to be Upper Miocene, but subsequently 'definitely ascertained to be Pliocene,' some of the flints are of purely natural and not artificial origin, so that two questions arise: First, were the fossil remains associ-

ated with the worked flints or with those of natural forms? And second, were they actually found in the bed to which they have been assigned, or did they merely lie together on the surface?

Even the *Pithecanthropus erectus* of Dr. Eugène Dubois from Java meets with some incredulous objectors from both the physiological and the geological sides. From the point of view of the latter the difficulty lies in determining the exact age of what are apparently alluvial beds in the bottom of a river valley.

When we return to Paleolithic man it is satisfactory to feel that we are treading on comparatively secure ground, and that the discoveries of the last forty years in Britain alone enable us to a great extent to reconstitute his history. We may not know the exact geological period when first he settled in the British area, but we have good evidence that he occupied it at a time when the configuration of the surface was entirely different from what it is at present; when the river valleys had not been cut down to anything like their existing depth; when the fauna of the country was of a totally different character from that of the present day; when the extension of the southern part of the island seaward was in places such that the land was continuous with that of the continent, and when in all probability a far more rainy climate prevailed. We have proofs of the occupation of the country by man during the long lapse of time that was necessary for the excavation of the river valleys. We have found the old floors on which his habitations were fixed; we have been able to trace him at work on the manufacture of flint instruments, and by building up the one upon the other the flakes struck off by the primæval workman in those remote times we have been able to reconstruct the blocks of flint which served as his material.

That the duration of the Palæolithic Period must have extended over an almost incredible length of time is sufficiently proved by the fact that valleys, some miles in width and of a depth of from 100 to 150 feet, have been eroded since the deposit of the earliest implement-bearing beds. Nor is the apparent duration of this period diminished by the consideration that the floods which hollowed out the valleys were not in all probability of such frequent occurrence as to teach Palæolithic man by experience the danger of settling too near to the streams, for had he kept to the higher slopes of the valley there would have been but little chance of his implements having so constantly formed constituent parts of the gravels deposited by the floods.

The examination of British cave-deposits affords corroborative evidence of this extended duration of the Paleolithic Period. In Kent's Cavern, at Torquay, for instance, we find in the lowest deposit, the breccia below the red cave-earth, implements of flint and chert corresponding, in all respects, with those of the high level and most ancient river gravels. In the cave-earth these are scarcer, though implements occur which also have their analogues in the river deposits; but, what is more remarkable, harpoons of reindeer's horn and needles of bone are present, identical in form and character with those of the caverns of the Reindeer Period in the south of France, and suggestive of some bond of union or identity of descent between the early troglodytes, whose habitations were geographically so widely separated the one from the other.

In a cavern at Creswell Crags, on the confines of Derbyshire and Nottinghamshire, a bone has, moreover, been found engraved with a representation of parts of a horse in precisely the same style as the engraved bones of the French caves.

It is uncertain whether any of the river-

drift specimens belong to so late a date as these artistic cavern-remains, but the greatly superior antiquity of even these to any Neolithic relics is testified by the thick layer of stalagmite which had been deposited in Kent's Cavern before its occupation by men of the Neolithic and Bronze Periods.

Towards the close of the period covered by the human occupation of the French caves there seems to have been a dwindling in the number of the larger animals constituting the Quaternary fauna, whereas their remains are present in abundance in the lower and, therefore, more recent of the valley gravels. This circumstance may afford an argument in favor of regarding the period represented by the later French caves as a continuation of that during which the old river gravels were deposited, and yet the great change in the fauna that has taken place since the latest of the cave-deposits included in the Paleolithic Period is indicative of an immense lapse of time.

How much greater must have been the time required for the more conspicuous change between the old Quaternary fauna of the river gravels and that characteristic of the Neolithic Period!

As has been pointed out by Professor Boyd Dawkins, only thirty-one out of the forty-eight well-ascertained species living in the post-Glacial or River-drift Period survived into pre-historic or Neolithic times. We have not, indeed, any means at command for estimating the number of centuries which such an important change indicates; but when we remember that the date of the commencement of the Neolithic or Surface Stone Period is still shrouded in the mist of a dim antiquity, and that prior to that commencement the River-drift Period had long come to an end; and when we further take into account the almost inconceivable ages that even under the most favorable conditions the excavation of wide and deep valleys by river action implies, the remoteness of the date at which the Paleolithic Period had its beginning almost transcends our powers of imagination.

We find distinct traces of river action from 100 to 200 feet above the level of existing streams and rivers, and sometimes at a great distance from them; we observe old fresh-water deposits on the slopes of valleys several miles in width; we find that long and lofty escarpments of rock have receded unknown distances since their summits were first occupied by Paleolithic man; we see that the whole side of a wide river valley has been carried away by an invasion of the sea, which attacked and removed a barrier of chalk cliffs from 400 to 600 feet in height; we find that what was formerly an inland river has been widened out into an arm of the sea, now the highway of our fleets, and that gravels which were originally deposited in the bed of some ancient river now cap isolated and lofty hills.

And yet, remote as the date of the first known occupation of Britain by man may be, it belongs to what, geologically speaking, must be regarded as a quite recent period, for we are now in a position to fix, with some degree of accuracy, its place on the geological scale. Thanks to investigations ably carried out at Hoxne in Suffolk, and at Hitchin in Hertfordshire, by Mr. Clement Reid, under the auspices of this Association and of the Royal Society, we know that the implement-bearing beds at those places undoubtedly belong to a time subsequent to the deposit of the great chalky boulder clay of the eastern counties of England. It is, of course, self-evident that this vast deposit, in whatever manner it may have been formed, could not, for centuries after its deposition was complete, have presented a surface inhabitable by man. Moreover, at a distance but little farther north, beds exist which also, though at a somewhat later date, were apparently formed under glacial con-

ditions. At Hoxne the interval between the deposit of the boulder clay and of the implement-bearing beds is distinctly proved to have witnessed at least two noteworthy changes in climate. The beds immediately reposing on the clay are characterized by the presence of alder in abundance, of hazel and yew, as well as by that of numerous flowering plants indicative of a temperate climate very different from that under which the boulder clay itself was formed. Above these beds characterized by temperate plants comes a thick and more recent series of strata, in which leaves of the dwarf arctic willow and birch abound, and which were in all probability deposited under conditions like those of the cold regions of Siberia and North America.

At a higher level and of more recent date than these—from which they are entirely distinct—are the beds containing Paleolithic implements, formed in all probability under conditions not essentially different from those of the present day. However this may be, we have now conclusive evidence that the Paleolithic implements are in the eastern counties of England of a date long posterior to that of the great chalky boulder clay.

It may be said, and said truly, that the implements at Hoxne cannot be shown to belong to the beginning rather than to some later stage of the Paleolithic Period. The changes, however, that have taken place at Hoxne in the surface configuration of the country prove that the beds containing the implements cannot belong to the close of that period.

It must, moreover, be remembered that in what are probably the earliest of the Paleolithic deposits of the eastern counties, those at the highest level, near Brandon in Norfolk, where the gravels contain the largest proportion of pebbles derived from Glacial beds, some of the implements themselves have been manufactured from materials not native to the spot, but brought from a distance, and derived in all probability either from the boulder clay or from some of the beds associated with it.

We must, however, take a wider view of the whole question, for it must not for a moment be supposed that there are the slightest grounds for believing that the civilization, such as it was, of the Paleolithic Period originated in the British Isles. We find in other countries implements so identical in form and character with British specimens that they might have been manufactured by the same hands. These occur over large areas in France under similar conditions to those that prevail in England. The same forms have been discovered in the ancient river gravels of Italy, Spain and Portugal. Some few have been recorded from Africa, and analogous types occur in considerable numbers in the south of that continent. On the banks of the Nile, many hundreds of feet above its present level, implements of the European types have been discovered; while in Somaliland, in an ancient river valley at a great elevation above the sea, Mr. Seton-Karr has collected a large number of implements formed of flint and quartzite, which, judging from their form and character, might have been dug out of the drift deposits of the Somme or the Seine, the Thames or the ancient Solent.

In the valley of the Euphrates implements of the same kind have also been found, and again farther east, in the lateritic deposits of southern India, they have been obtained in considerable numbers. It is not a little remarkable, and is at the same time highly suggestive, that a form of implement almost peculiar to Madras reappears among implements from the very ancient gravels of the Manzanares at Madrid. In the case of the African discoveries we have as yet no definite paleontological evidence by which to fix their antiquity,

but in the Narbadá valley of western India Paleolithic implements of quartzite seem to be associated with a local fauna of Pleistocene age, comprising, like that of Europe, the elephant, hippopotamus, ox and other mammals of species now extinct. A correlation of the two faunas with a view of ascertaining their chronological relations is beset with many difficulties, but there seems reason for accepting this Indian Pleistocene fauna as in some degree more ancient than the European.

Is this not a case in which the imagination may be fairly invoked in aid of science? May we not from these data attempt, in some degree, to build up and reconstruct the early history of the human family? There, in eastern Asia, in a tropical climate, with the means of subsistence readily at hand, may we not picture to ourselves our earliest ancestors gradually developing from a lowly origin, acquiring a taste for hunting, if not indeed being driven to protect themselves from the beasts around them, and evolving the more complicated forms of tools or weapons from the simpler flakes which had previously served them as knives? May we not imagine that, when once the stage of civilization denoted by these Paleolithic implements had been reached, the game for the hunter became scarcer, and that his life, in consequence, assumed a more nomad character? Then, and possibly not till then, may a series of migrations to 'fresh woods and pastures new' not unnaturally have ensued, and these, following the usual course of 'westward towards the setting sun,' might eventually lead to a Paleolithic population finding its way to the extreme borders of western Europe, where we find such numerous traces of its presence.

How long a term of years may be involved in such a migration it is impossible to say, but that such a migration took place the phenomena seem to justify us in believing. It can hardly be supposed that the process that I have shadowed forth was reversed, and that man, having originated in northwestern Europe, in a cold climate, where clothing was necessary and food scarce, subsequently migrated eastward to India and southward to the Cape of Good Hope! As yet, our records of discoveries in India and eastern Asia are but scanty; but it is there that the traces of the cradle of the human race are, in my opinion, to be sought, and possibly future discoveries may place upon a more solid foundation the visionary structure that I have ventured to erect.

It may be thought that my hypothesis does not do justice to what Sir Thomas Browne has so happily termed 'that great antiquity, America.' I am, however, not here immediately concerned with the important Neolithic remains of all kinds with which this great continent abounds. I am now confining myself to the question of Paleolithic man and his origin, and in considering it I am not unmindful of the Trenton implements, though I must content myself by saying that the 'turtle-back' form is essentially different from the majority of those on the wide dissemination of which I have been speculating, and, moreover, as many here present are aware, the circumstances of the finding of these American implements are still under careful discussion.

Leaving them out of the question for the present, it may be thought worth while to carry our speculations rather further, and to consider the relations in time between the Paleolithic and the Neolithic Periods. We have seen that the stage in human civilization denoted by the use of the ordinary forms of Paleolithic implements must have extended over a vast period of time if we have to allow for the migration of the primeval hunters from their original home, wherever it may have been in Asia

or Africa, to the west of Europe, including Britain. We have seen that, during this migration, the forms of the weapons and tools made from silicious stones had become, as it were, stereotyped, and further, that, during the subsequent extended period implied by the erosion of the valleys, the modifications in the form of the implements and the changes in the fauna associated with the men who used them were but slight.

At the close of the period during which the valleys were being eroded comes that represented by the latest occupation of the caves by Paleolithic man, when both in Britain and in the south of France the reindeer was abundant; but among the stone weapons and implements of that long troglodytic phase of man's history not a single example with the edge sharpened by grinding has as yet been found. All that can safely be said is that the larger implements as well as the larger mammals had become scarcer, that greater power in chipping flint had been attained, that the arts of the engraver and the sculptor had considerably developed, and that the use of the bow had probably been discovered.

Directly we encounter the relics of the Neolithic Period, often, in the case of the caves lately mentioned, separated from the earlier remains by a thick layer of underlying stalagmite, we find flint hatchets polished at the edge and on the surface, cutting at the broad and not at the narrow end, and other forms of implements associated with a fauna in all essential respects identical with that of the present day.

Were the makers of these polished weapons the direct descendants of Paleolithic ancestors whose occpation of the country was continuous from the days of the old river gravels? or had these long since died out, so that after western Europe had for ages remained uninhabited it was repeopled in Neolithic times by the immigration of some new race of men? Was there, in fact, a 'great gulf fixed' between the two occupations? or was there in Europe a gradual transition from the one stage of culture to the other?

It has been said that "what song the Syrens sang, or what name Achilles assumed when he hid himself among women, though puzzling questions, are not beyond all conjecture;" and though the questions now proposed may come under the same category, and must await the discovery of many more essential facts before they receive definite and satisfactory answers, we may, I think, throw some light upon them if we venture to take a few steps upon the seductive if insecure paths of conjecture. So far as I know, we have as yet no trustworthy evidence of any transition from the one age to the other, and the gulf between them remains practically unbridged. We can, indeed, hardly name the part of the world in which to seek for the cradle of Neolithic civilization, though we know that traces of what appear to have been a stone-using people have been discovered in Egypt, and that what must be among the latest of the relics of their industry have been assigned to a date some 3,500 to 4,000 years before our era. The men of that time had attained to the highest degree of skill in working flint that has ever been reached. Their beautifully made knives and spear-heads seem indicative of a culminating point reached after long ages of experience; but whence these artists in flint came or who they were is at present absolutely unknown, and their handiworks afford no clue to help us in tracing their origin.

Taking a wider survey, we may say that, generally speaking, not only the fauna, but the surface configuration of the country were, in western Europe at all events, much the same at the commencement of the Neolithic Period as they are at the present day. We have, too, no geological

indications to aid us in forming any chronological scale.

The occupation of some of the caves in the south of France seems to have been carried on after the erosion of the neighboring river valleys had ceased, and so far as our knowledge goes these caves offer evidence of being the latest in time of those occupied by man during the Paleolithic Period. It seems barely possible that, though in the north of Europe there are no distinct signs of such late occupation, yet that, in the south, man may have lived on, though in diminished numbers; and that in some of the caves, such, for instance, as those in the neighborhood of Mentone, there may be traces of his existence during the transitional period that connects the Paleolithic and Neolithic Ages. If this were really the case we might expect to find some traces of a dissemination of Neolithic culture from a north Italian center, but I much doubt whether any such traces actually exist.

If it had been in that part of the world that the transition took place, how are we to account for the abundance of polished stone hatchets found in central India? Did Neolithic man return eastward by the same route as that by which in remote ages his Paleolithic predecessor had migrated westward? Would it not be in defiance of all probability to answer such a question in the affirmative? We have, it must be confessed, nothing of a substantial character to guide us in these speculations; but, pending the advent of evidence to the contrary, we may, I think, provisionally adopt the view that, owing to the failure of food, climatal changes or other causes, the occupation of western Europe by Paleolithic man absolutely ceased, and that it was not until after an interval of long duration that Europe was re-peopled by a race of men immigrating from some other part of the globe where the human race had survived, and in course of ages had developed a higher stage of culture than that of Paleolithic man.

I have been carried away by the liberty allowed for conjecture into the regions of pure imagination, and must now return to the realms of fact, and one fact on which I desire for a short time to insist is that of the existence at the present day, in close juxtaposition with our own civilization, of races of men who, at all events but a few generations ago, lived under much the same conditions as did our own Neolithic predecessors in Europe.

The manners and customs of these primitive tribes and peoples are changing day by day, their languages are becoming obsolete, their myths and traditions are dying out, their ancient processes of manufacture are falling into oblivion, and their numbers are rapidly diminishing, so that it seems inevitable that ere long many of these interesting populations will become absolutely extinct. The admirable Bureau of Ethnology instituted by our neighbors in the United States of America has done much towards preserving a knowledge of the various native races in this vast continent, and here in Canada the annual Archæological Reports presented to the Minister of Education are rendering good service in the same cause.

Moreover, the committee of this Association appointed to investigate the physical characters, languages and industrial and social conditions of the Northwestern tribes of the Dominion of Canada is about to present its twelfth and final report, which, in conjunction with those already presented, will do much towards preserving a knowledge of the habits and languages of those tribes. It is sad to think that Mr. Horatio Hale, whose comprehensive grasp of the bearings of ethnological questions, and whose unremitting labors have so materially conduced to the success of the com-

mittee, should be no longer among us. Although this report is said to be final, it is to be hoped that the committee may be able to indicate lines upon which future work in the direction of ethnological and archæological research may be profitably carried on in this part of Her Majesty's dominions.

It is, however, lamentable to notice how little is being or has been officially done towards preserving a full record of the habits, beliefs, arts, myths, languages and physical characteristics of the countless other tribes and nations more or less uncivilized which are comprised within the limits of the British Empire. At the meeting of this Association held last year at Liverpool it was resolved by the General Committee "that it is of urgent importance to press upon the government the necessity of establishing a Bureau of Ethnology for Greater Britain, which, by collecting information with regard to the native races within and on the borders of the Empire, will prove of immense value to science and to the government itself." It has been suggested that such a bureau might, with the greatest advantage and with the least outlay and permanent expense, be connected either with the British Museum or with the Imperial Institute, and the project has already been submitted for the consideration of the trustees of the former establishment.

The existence of an almost unrivalled ethnological collection in the Museum, and the presence there of officers already well versed in ethnological research, seem to afford an argument in favor of the proposed bureau being connected with it. On the other hand, the Imperial Institute was founded with an especial view to its being a center around which every interest connected with the dependencies of the Empire might gather for information and support. The establishment, within the last twelve months of a scientific department within the Institute, with well-appointed laboratories and a highly trained staff, shows how ready are those concerned in its management to undertake any duties that may conduce to the welfare of the outlying parts of the British Empire; a fact of which I believe that Canada is fully aware. The Institute is, therefore, likely to develop, so far as its scientific department is concerned, into a bureau of advice in all matters scientific and technical, and certainly a Bureau of Ethnology, such as that suggested, would not be out of place within its walls.

Wherever such an institution is to be established, the question of its existence must, of necessity, rest with Her Majesty's government and treasury, inasmuch as without funds, however moderate, the undertaking cannot be carried on. I trust that in considering the question it will always be borne in mind that in the relations between civilized and uncivilized nations and races it is of the first importance that the prejudices, and especially the religious or semi-religious and caste prejudices, of the latter should be thoroughly well known to the former. If but a single 'little war' could be avoided in consequence of the knowledge acquired and stored up by the Bureau of Ethnology preventing such a misunderstanding as might culminate in warfare, the cost of such an institution would quickly be saved.

I fear that it will be thought that I have dwelt too long on primeval man and his modern representatives, and that I should have taken this opportunity to discuss some more general subject, such as the advances made in the various departments of science since last this Association met in Canada. Such a subject would, no doubt, have afforded an infinity of interesting topics on which to dilate. Spectrum analysis, the origin and nature of celestial bodies, photography, the connection between heat, light and elec-

tricity, the practical applications of the latter, terrestrial magnetism, the liquefaction and solidification of gases, the behavior of elements and compounds under the influence of extreme cold, the nature and uses of the Röntgen rays, the advances in bacteriology and in prophylactic medicine, might all have been passed under review, and to many of my audience would have seemed to possess greater claims to attention than the subject that I have chosen.

It must, however, be borne in mind that most, if not indeed all, of these topics will be discussed by more competent authorities in the various Sections of the Association by means of the Presidential addresses or otherwise. Nor must it be forgotten that I occupy this position as a representative of archæology, and am therefore justified in bringing before you a subject in which every member of every race of mankind ought to be interested—the antiquity of the human family and the scenes of its infancy.

Others will direct our thoughts in other directions, but the farther we proceed the more clearly shall we realize the connection and inter-dependence of all departments of science. Year after year, as meetings of this Association take place, we may also foresee that 'many shall run to and fro and knowledge shall be increased.' Year after year advances will be made in science and in reading that Book of Nature that lies ever open before our eyes ; successive stones will be brought for building up that Temple of Knowledge of which our fathers and we have labored to lay the foundations. May we not well exclaim with old Robert Recorde?—

"Oh woorthy temple of Goddes magnificence : Oh throne of glorye and seate of the lorde : thy substance most pure what tonge can describe? thy signes are so wonderous, surmountinge mannes witte, the effects of thy motions so diuers in kinde: so harde for to searche, and worse for to fynde—Thy woorkes are all wondrous, thy cunning unknowen : yet seedes of all knowledge in that booke are sowen—And yet in that boke who rightly can reade, to all secrete knowledge it will him straighte leade."*

AMERICAN ASSOCIATION FOR ADVANCEMENT OF SCIENCE: FORTY-SIXTH MEETING, DETROIT, AUGUST 7–13, 1897.

The second Detroit meeting of the American Association for the Advancement of Science began on Saturday, August 7, 1897, with a slimly attended meeting of the Council at the Hotel Cadillac. As last year, the first general session was held Monday morning, and the last on Friday evening. The general sessions and all meetings of sections were held in the new Central High School building, which is excellently adapted for the purpose. Superintendent Bliss and the school authorities made every effort to assist the Association.

Monday evening a reception to the Association was given at the High School by the local committee. Thursday afternoon Section G, together with the officers and guests of the Association, were invited to a garden party by Mr. Joseph Berry, of Grosse Pointe. Friday evening there was a reception at the High School building after the final session, and Saturday, August 14th, was given to an excursion to the Ste Claire flats.

The arrangements and management of the local committee were excellent in every respect, and the Detroit meeting, which it was feared would be a failure, was a very successful one. On account of the meeting of the British Association at Toronto, the attendance at Detroit was small, the total registration being only 291. There were present a number of foreign guests, among them being Messrs. A. G. Greenhill, W. E. Hoyle, A. W. Scott, J. Thorp, D. H. Mar-

*Preface to Robert Recorde's *Castle of Knowledge*, 1556.

shall, W. Doberck, R. Munro, R. Gowing, A. B. Macallum, A. G. Vernon-Harcourt, W. Duddell, J. L. Myres, A. Penck, E. B. Poulton and Prince Krapotkin. There were elected 126 new members, and 50 members were made fellows.

On account of the death of retiring President Cope, the Monday morning session was opened by Dr. Theodore Gill, the senior Vice-President of the Buffalo meeting. He introduced W J McGee, acting President of the Detroit meeting and serving in the place of Dr. Wolcott Gibbs, who was ill and was forbidden by his physician to be present. The vacancies in the chairmanships of Sections F and E, Zoology and Geology, caused by the decease of G. Browne Goode and the absence of Professor White, were filled by the selection of L. O. Howard and E. W. Claypole.

Besides the morning meetings, the Council held three long evening sessions. It was urged very strongly that the methods of business procedure of the Association needed to be simplified, and as the first step in this direction certain amendments proposed before the general session in 1896 were recommended for passage by the Association and after presentation to it were passed. These amendments leave the selection of officers and the fixing of the place of meeting wholly in the hands of the Nominating Committee. Also, the power of Council was somewhat extended, the plan being to give it still further powers.

Section H, Anthropology, was granted permission by the Council to hold a winter meeting.

Messrs. Colburn, Morse, Prescott, Woodward and Howard were appointed a committee to secure uniform nomenclature in scientific terms used in commerce. A report prepared by Mr. Colburn was accepted by the committee, and the Council ordered the report to be printed by the Permanent Secretary.

The movement to raise funds for a statue of Gallileo Ferraris was recommended to the favorable consideration of the Association.

The action taken at the Buffalo meeting, whereby the annual volume was considerably abridged, was repealed.

A grant of $100 from the research fund was made to the marine biological laboratory at Woods Holl, the committee on the laboratory for 1898 to consist of the outgoing and incoming Vice-Presidents of Sections F and G, together with the director of the laboratory.

The following were appointed a committee on extending the influence of the Association into the secondary schools: E. S. Morse, W. Orr, Jr., T. C. Chamberlin.

The special committees of the Association were continued, the personnel of *4*, on the policy of the Association, being changed slightly, so as to consist of the President, Permanent Secretary and Treasurer, *ex-officio*, together with Messrs. L. O. Howard, W. H. Brewer, T. C. Mendenhall and Mansfield Merriman. No report was received from *6*, on standard colors and standard nomenclature of colors, but it was understood that much work had been done by the committee.

On Friday morning, in general session, the resignation of Permanent Secretary Putnam was announced. Also, the selection of Boston as the place of meeting for 1898, the jubilee year of the Association. Also, the choice of the following officers for 1898:

President—F. W. Putnam, Cambridge, Mass.

Permanent Secretary—L. O. Howard, Washington, D. C.

General Secretary—D. S. Kellicott, Columbus, O.

Council Secretary—F. Bedell, Ithaca, N. Y.

Treasurer—R. S. Woodward, New York.

Vice-Presidents—Mathematics and As-

tronomy, E. E. Barnard, University of Chicago; Physics, Frank P. Whitman, Adelbert College, Cleveland; Chemistry, Edgar F. Smith, University of Pennsylvania; Mechanical Science and Engineering, M. E. Cooley, University of Michigan; Geology and Geography, H. L. Fairchild, Rochester University; Zoology, A. S. Packard, Brown University, Providence, R. I.; Botany, W. F. Farlow, Harvard University; Anthropology, J. McKeen Cattell, Columbia University; Economic Science and Statistics, Archibald Blue, Director of Bureau of Mines, Toronto, Canada.

Secretaries of the Sections—Mathematics and Astronomy, Alexander Ziwet, University of Michigan; Physics, E. B. Ross, Wesleyan University; Chemistry, Charles Baskerville, University of North Carolina; Mechanical Science and Engineering, Wm. S. Aldrich, University of West Virginia; Geology and Geography, Warren Upham, St. Paul, Minn; Zoology, C. W. Stiles, Department of Agriculture, Washington, D. C.; Botany, Erwin F. Smith, Department of Agriculture, Washington, D. C.; Anthropology, M. H. Saville, American Museum of Natural History, New York City; Economic Science and Statistics, Marcus Benjamin, U. S. National Museum, Washington, D. C.

On Friday evening there was a general session at which the usual complimentary resolutions were passed, after which the 46th meeting of the Association was declared adjourned. As has been said, this was an unusually good meeting. The scientific papers were above the average, and the sections were well attended by citizens of Detroit as well as by members. A number of the distinguished foreign guests gave papers and took part in the discussions.

During the Association week meetings were held by the American Chemistry Society, the Society for the Promotion of Agricultural Science, the Society of Economic Entomologists and the Michigan Academy of Sciences. Some of these meetings were held jointly with sections of the American Association. It is believed that by offering proper courtesies to the affiliated societies more of these joint meetings can be held, to the great advantage of the Association and of the societies themselves.

ASAPH HALL, JR.,
General Secretary.

CURRENT NOTES ON PHYSIOGRAPHY.

THE ATHABASCA REGION.

TYRRELL'S report on the country between Athabasca lake and Churchill river (Geol. Surv. Canada, Ann. Rep., VIII., for 1895–1897) divides the region into Archæan and Cambrian areas. The first is occupied by low rocky hills and ridges from fifty to a hundred and fifty feet in local relief, separated by drift-covered depressions, wooded or interrupted by small irregular lakes. The second is a monotonous district of horizontal sandstones, forming a sterile plain, thinly wooded, with few lakes. The absence of deep valleys and the occurrence of lakes and rapids shows that the drainage is very new. It is suggested that Athabaska lake occupies a pre-glacial valley, excavated along the northern boundary of the sandstone area, when the land thereabouts stood higher or sloped more to the west. Till is scanty on the Archæan area, but more plentiful on the sandstone plain. Rugged moraines are found further southwest, like Duck and Riding mountains, in Manitoba. The most interesting drift hills of the region are steep, narrow ridges, half a mile or more in length, averaging 120 feet in height, standing parallel to the line of glacial motion and rounding down gently at both ends. Unlike drumlins, they consist of unassorted rock flour mixed with boulders, and they all lie on the floors of large post-glacial lakes, now drained. They are explained as deposits in quiet water occupying ice gorges, and Tyrell calls them

'ispatinows,' the Cree work for a conspicuous hill. They seem to be similar to the 'paha' described by McGee in Iowa. The prefix 'Hyper' is used with the name of existing lakes, to indicate their glacial expansion to greater height and area.

SENECA COUNTY, N. Y.

THE Annual Report of the State Geologist of New York for 1894 (lately received) contains an account of Seneca county by D. F. Lincoln. The northern part of the county includes a part of the Ontario plain, varied chiefly by long narrow drumlins. Southward from the plain a gradual ascent is made to the upland, here dissected by the deep sub-parallel troughs of Cayuga and Seneca lakes. Near the southern border, great flat hills rise several hundred feet above the upland, these being outliers of Portage strata from the higher Allegheny plateau further south. The slope from the upland into the lake troughs is notably smooth, being furrowed only by post-glacial ravines in which cliffs and falls are picturesquely developed; but in pre-glacial time the slopes must have been more furrowed, inasmuch as several side valleys now appear to be obliterated by drift filling.

DRAINAGE MAP OF RHODE ISLAND.

THE 18th Annual Report of the Rhode Island Board of Health contains a contour map of the drainage areas on a scale of four miles to an inch, based on the topographical State map and prepared by D. W. Hoyt. The terminal moraine near the south coast forms a divide by which the Pawcatuck and its tributaries from among the hills are turned westward, instead of flowing directly to the ocean. It is noted that Moshassuck valley, west of Providence, was probably the pre-glacial course of the Blackstone, which now flows east of the city into the head of Narragansett bay. The present course of the river is interrupted by ledges, furnishing water power that is actively employed at Valley Falls and Pawtucket; the inferred pre-glacial course is obstructed by drift, in which driven wells are supplied with water from a 'subterranean Blackstone.'

POPOCATAPETL AND IXTACCIHUATL.

A SERIES of interesting and well illustrated observations on the two great Mexican mountains, by O. C. Farrington, forms publication 18 of the Field Columbian Museum, of Chicago (Geol. Series, Vol. I., No. 2). The upper cone of Popocatapetl, clothed with sand and snow, has a nearly uniform slope; the middle portion is carved by numerous channels; "the lower portion is involved in the tortuous folds which make up the Sierra." The summit crater is a pit, 2,000 feet in greater diameter, 1,300 feet in lesser diameter, and from 800 to 1,500 feet deep, from whose walls of discordant lava beds and breccia rocks continually fall to the bottom. The cumulus clouds that frequently envelop the mountain flank in the afternoon are (erroneously?) ascribed to cooling caused by snow. Ixtaccihuatl is described as of more massive and uniform structure, and without distinct crater, as if the product of fissure erruption; but as mention is made of lava beds on its flanks, weathered to deep soil near the base and dissected into ragged spurs on the slopes, it seems possible that long continued erosion may be the chief cause of its unlikeness to volcanoes of more ordinary form. The snow reservoirs near the summits suggest the same conclusion.

WADIS OF TRIPOLI.

FURTHER notes on the Tripoli hill range, by H. S. Cowper (London Geogr. Journ., IX., 1897, 620–638), contain, among other items, a number of illustrations and brief descriptions of the wadis that descend toward the Mediterranean coast. They dissect the hill country, emerging by gate-

like outlets in its north-facing escarpment, and then traverse a sloping plain that descends to a barren sandy strip before reaching the sea. They form the natural paths of travel by which the hill tribesmen always go to and from the coast.

Harvard University.

CURRENT NOTES ON ANTHROPOLOGY.

STUDIES IN MAYAN HIEROGLYPHS.

It is as agreeable as it is rare to find a sane student of the Mayan hieroglyphs. For that reason among others it is pleasurable to mention several articles which have appeared lately from the pen of Mr. Lewis W. Gunckel, of Dayton, Ohio.

Two of these are in the *American Antiquarian* for the present year. They are entitled, 'The numeral signs in the Palenque tablets,' and 'An Analysis of the day-signs in the Palenquen inscriptions.' A third is in the *American Anthropologist* for May on, 'The direction in which Mayan inscriptions should be read.' All of these indicate thorough investigation and calm judgment, as well as a good acquaintance with what his predecessors in the field have accomplished. The method pursued is scientific and the presentation of the results temperate.

Of course, some of such results may have to be modified by future research, and they may not be good in all cases, that is, in other parts of the field; but the plan which Mr. Gunckel has adopted of approaching these intricate problems is one sure to be productive of additions to our positive knowledge concerning them.

PRIMITIVE DECORATIVE ART.

For the analysis of primitive art-motives no paper has appeared for a long while more instructive than that by Dr. Franz Boas in the Bulletin of the American Museum of Natural History, Vol. IX., entitled 'The decorative art of the Indians of the North Pacific Coast.' The tribes whom he has in view are celebrated for the abundance of their painting and sculpture, their totem poles, colored dishes and carved pipes, and all are somewhat familiar with their strange and perplexing designs. These are analyzed in the article referred to with masterly skill, and the text is furnished with ample and accurate illustrations, which enable the reader to follow the demonstration step by step.

Certain general principles furnish the key to these primitive art-motives. It was the aim of the artist to bring into prominence the most specific feature of the animal he drew, and yet to show as much of the whole of it as he could. As he knew nothing of perspective, he resorted to the most curious devices to accomplish his aim. He represented his subject in sections and distortions, and sometimes by its specific feature reduced to a mere symbol, as a beaver by its incisor teeth only. Many of these devices belong to primitive art generally, and hence this paper will efficiently aid the student in other fields than the Northwest Coast.

University of Pennsylvania.

SCIENTIFIC NOTES AND NEWS.

We publish elsewhere a full report, by the General Secretary, of the Detroit meeting of the American Association for the Advancement of Science. Although the attendance was small, the scientific programs were in many sections unusually strong and promise well for the future of the Association. A notable meeting on the occasion of the fiftieth anniversary of the Association next year at Boston, with Professor Putnam as President and Mr. Howard as Permanent Secretary, is assured.

We are glad to be able to publish in this issue the address of the President of the British Association, given on Wednesday of this week. The addresses of the Presidents of the Sections

were of great interest. These were in most cases on general topics, and in accordance with the custom of the Association a special title was not given to most of the addresses and the subjects were withheld until they were delivered. The programs promise the discussion of many interesting topics, American men of science being well represented.

THE French journals publish the programs for the meeting of the French Association for the Advancement of Science, held last week at Saint-Étienne. There were fifteen papers presented in mathematics, fifteen in the physical and chemical sciences, seventy-two in the natural sciences and twenty-eight in the economic sciences. Many interesting topics were brought forward, but, contrary to the usual programs of the British Association, there is a noticeable absence of the names of French men of science having an international reputation. The Association appears, however, to be in a flourishing condition as regards number of members and finances, the annual receipts amounting to nearly $20,000.

THE British Treasury has appointed a committee "to consider and report upon the desirability of establishing a National Physical Laboratory for the testing and verification of instruments for physical investigation, for the construction and preservation of standards of measurement, and for the systematic determination of physical constants and numerical *data* useful for scientific and industrial purposes, and to report whether the work of such an institution, if established, could be associated with any testing or standardizing work already performed wholly or partly at the public cost." The members of the committee are: Lord Rayleigh (chairman), Sir Courtenay Boyle, Sir Andrew Noble, Sir John Wolfe Barry, W. C. Roberts-Austen, Esq., Robert Chalmers, Esq., A. W. Rücker, Esq., Alexander Siemens, Esq., and T. E. Thorpe, Esq.

THE bill regarding the use of the metric system in Great Britain has been passed by the House of Lords.

THE American Museum of Natural History, New York, has been presented with two fine collections of butterflies. Mr. William Shaus, formerly of New York, but now resident in London, has given his collection of tropical butterflies, said to contain over 10,000 specimens and valued at $20,000. Dean E. A. Hoffman, of the General Theological Seminary, New York, is the other donor, and his collection is said to be complete with regard to North American species.

THE Arnold Aboretum, Harvard University, has received from Miss Abbey A. Bradley, of Hingham, Mass., a gift of $20,000. The money has been given in memory of her father, the late William L. Bradley, the income to be used in scientific investigations on arboriculture.

THE British House of Commons has voted £809,992 for the Department of Science and Art and £162,439 for the British Museum.

M. FALGUIÈRE has now completed his model for the statue of Pasteur. It is expected that the Municipal Council will permit the erection of the statue on the space between the Panthéon and l'Odéon.

DR. JOSEPH J. KINYOUN, of the U. S. Marine Hospital Service, has been designated by the Secretary of the Treasury as a delegate to the International Conference on Leprosy, to be held at Berlin during October, and has also been directed to visit the Continental bacteriological laboratories for the information of the Marine Hospital Service.

MR. T. I. POCKOCK has been appointed Assistant Geologist in the British Geological Survey. Dr. W. F. Hume and Mr. L. Gorringe have been appointed assistants of the Geological Survey of Egypt, the work of which, as we announced last week, has been greatly enlarged.

THE Brooklyn Institute announces that Dr. Fridjof Nansen is one of the lecturers engaged for the coming season.

THE Royal College of Physicians, London, has conferred the Moxon gold medal on Sir Samuel Wilks, President of the College, for his work in clinical medicine, and the Baly medal on Professor Schäfer, for his work in physiology.

THE Civil Service Commission announce a vacancy in the position of computor in the

office of the Coast and Geodetic Survey, and several vacancies in the position of fish culturist. Details can be obtained by application to the Commission.

Professor Langley was present at the meeting of the Paris Academy of Sciences on August 2d, and was welcomed by the President and M. Berthelot. Professor Langley gave an account of the results of his experiments with the aërodrome.

Lord Kelvin arrived in New York last Friday on the 'Campania.' He will return to New York on his way home after the meeting of the British Association and a visit to Nova Scotia.

The second International Bibliographical Conference opened its proceedings, under the presidency of M. le Chevalier Descamps David and M. Lafontaine, at Brussels on August 2d. At the opening session the delegates gave an account of bibliographical progress in their respective countries.

The conference of South African States on the rinderpest was opened at Pretoria on August 2d, with Mr. Schutte as chairman. Rinderpest is reported to have destroyed the buffalo in North Matabeleland. The natives state that since the disappearance of the buffalo the tsetse fly has been unknown in the fly belt.

The British Institute of Mechanical Engineers celebrated, beginning on July 29th, the fiftieth anniversary of its foundation. The meeting was at Birmingham, where the Institute was founded and where it had its headquarters until 1877, when it was removed to London. The President, Mr. E. Windsor Richards, gave an account of the history of the Institute, with special reference to the presidents, beginning with George Stevenson. A gift of £3,000 was voted to the retiring Secretary, Mr. Bache, in recognition of his services which have contributed so greatly to the success of the Institute.

The Third International Congress of Sociology met at the Sorbonne, Paris, during the last week in July, under the presidency of M. Paul de Lilienfeld, Senator of the Russian Empire.

We learn from the *Revue Scientifique* that M. Louis Adrien Levat, President of the *Ligue Française ornithophile*, having its headquarters in Aix-en-Provençe, is engaged in organizing an international congress for the protection of insectiverous birds. It is proposed to hold the congress in October next and foreign societies are invited to send delegates.

The Sixteenth Congress of the Sanitary Institute of Great Britain will be held at Leeds from the 14th to the 18th of September, under the presidency of Dr. Robert Farquharson, M. P. An exhibition will be held in connection with the Congress.

The commissioners for the Exhibition of 1851 have made appointments to Science Research Scholarships for the year 1897, on the recommendation of the authorities of the respective universities and colleges. The scholarships are of the value of £150 a year, and are ordinarily tenable for two years in any university at home or abroad. The scholars are to devote themselves exclusively to study and research in some branch of science, the extension of which is important to the industries of the country. A limited number of the scholarships are renewed for a third year where it appears that the renewal is likely to result directly in work of scientific importance. This year three scholars have been reappointed for a third term, fourteen have been reappointed for a second term, and nineteen new appointments have been made. The Scholarships Committee consisted of Sir Henry Roscoe, chairman, Lord Rayleigh, Lord Kelvin, Lord Playfair, the late Mr. Mundella, Dr. William Garnett and Sir J. Norman Lockyer.

The John Lucas Walker studentship of pathology at Cambridge is vacant and candidates are invited to send applications to Dr. A. A. Kanthack, Cambridge, not later than October 15th. The scholarship is for original research in pathology and is of the annual value of £250, tenable for three years. It is open to women as well as men.

It is well known that before the success of the Atlantic Cable a company was formed to establish communication with Europe by an overland telegraph line via Alaska and Siberia,

and surveys in Alaska were made for this purpose. Mr. R. A. Fessenden contributes an article to the *Electrical World* raising the question of reviving the plan for such a telegraph line. He maintains that commerce with the East would justify the cost and that high speed systems of telegraphy would give it a great advantage over sub-marine cables even in communication between America and Europe.

THE Appalachian Mountain Club of Boston, has arranged an excursion to the Isle of Shoals, N. H., leaving Boston by special car at 9:40 a. m. on September 4th, returning on September 7th.

IT is reported that the biological expedition of Columbia University returning from Alaska lost its specimens and instruments in the wreck of the steamship *Mexico*. It was also reported that the anthropological expedition of the Field Columbia Museum had lost the extensive collections secured in Alaska, but this appears to be incorrect.

IT is stated in the *Scientific American* that Mr. H. P. Flower, Mayor of New Orleans, has just returned from Paris, where he went in order to study the Bertillon system for the identification of criminals. The system will be adopted in New Orleans, and will be taught to the police captains by Mr. Flower.

WE recorded last spring the sale of a great auk's egg for £294. Though the subiect has, perhaps, no greater scientific interest than that of the sale of a rare postage stamp, it may be noticed that another of the eggs, slightly cracked, has been sold in London for £168. The purchaser, Mr. Middlebrook, has now three specimens in his collection.

THE recent French motor-car race from Paris to Dieppe showed an advance, in that the carriages were not entered by the makers, but by the owners. Fifty-nine carriages started, the winner traversing the distance of ninety-three and three-fourths miles in scarcely more than four hours. There was only one steam-carriage and none with electrical motor, oil being used in fifty-eight of the fifty-nine carriages.

THE issue of the *Scientific American* for August 7th very properly criticises another journal for publishing a story about an English lady who lost her diamond ring in the dough of a cake and found it by means of X-rays, remarking that "this very improbable story doubtless originated in the brain of some reporter." It happens, however, that a few pages further on in the same issue the *Scientific American* publishes a long article translated from a French illustrated journal on the X-rays in the custom house. The article contains elaborate illustrations of the radioscopic examination of a valise, of the detection of a smuggler, etc. The facts of the matter are that M. Pallin, the Director of Customs, has considered the possibility of using X-rays in certain special cases, but the detailed accounts and the alleged photographs of the article evidently 'originated in the brain of some reporter.'

JACOB NORTH & Company, Lincoln, Neb., announce that they have in press the Phytogeography of Nebraska, by Dr. Roscoe Pound, Director of the Biological Survey of Nebraska, and Mr. F. E. Clements, assistant instructor in botany in the University of Nebraska. It is the first volume of a series intended to present in a number of volumes the results of the investigation of the floral covering of Nebraska, which has been in progress for the past five years in the Botanical Survey of that State. The volume deals primarily with phytogeographical problems in Nebraska, but gives a general treatment of the phytogeographical principles relating to distributional statistics, regional limitation, vegetation forms, habitat groups, plant formations, etc.

A CIRCULAR has been issued announcing a journal entitled *Intermédiare des biologistes*, intended to be an international organ for zoology, botany, physiology and psychology. The journal will be edited by M. Alfred Binet, the well-known French psychologist, with the help of two of his psychological assistants, MM. Victor Henri and N. Vaschide, and will be published on the 5th and 20th of each month by Schleicher Frères, Paris. The date when the publication will begin and the price are not given. The journal proposes to cover six departments : A bulletin of notes and news, questions and answers, abstracts, preliminary notices, one short original article and new apparatus.

THE *Zeitschrift für Psychologie und Physiologie der Sinnesorgane*, edited by Professors H. Ebbinghaus and Arthur König, and published since its foundation by Leopold Voss, Hamburg, will hereafter be published by J. A. Barth, Leipzig. The same publisher will also assume the publication of the continuation of Professor J. von Kries' 'Abhandlungen zur Physiologie der Gesichtsempfindungen' and of Helmholtz's 'Vorlesungen über Theoretische Physik,' of which latter work they hope to publish two further volumes during the coming year.

WE are glad to note the establishment of a monthly scientific journal at DeLand, Fla., entitled *Studies from Nature*. Although the subscription price is only 50 cents per annum, we fear that the publishers will not succeed in securing the 50,000 subscribers that they expect. Such local journals devoted to the natural sciences as they appeal to amateurs are healthful signs of an interest in what the conductors of this journal call 'The Wonders and Beauties of Nature.'

DR. W. FLINDERS PETRIE, the Egyptologist, has sent, according to the daily papers, to Dr. Breasod, of the University of Chicago, a valuable collection of relics excavated along the Nile. Among these are statues of Nen Khefea, a wealthy nobleman, and his wife, which are said to be nearly 5,000 years old. They are of limestone and are remarkably well preserved. They will go to the Haskell Oriental Museum of the University.

WE learn from *Natural Science* that the Zoological Museum of the Royal Academy of Science, St. Petersburg, has acquired thirty-three specimens of fossil bones and numerous remains of Post-Tertiary mammals collected by J. Savenkov at Krasnoyarsk. Among them are some bones and a piece of skin of *Rhinoceros tichorhinus*, which were taken from a well-preserved specimen of a rhinoceros, covered with skin, found 60 versts east of Kasatschje, on the bank of the Charaula, a left tributary of the Tomskaia. Dr. G. Stefanescu, the eminent Roumanian geologist, has discovered two portions of the mandible of a species of *Camelus* in an undoubted Quaternary gravel, six meters below the surface on the river bank of the Olt at Milcovul-de-jos, near Slatina, Roumania. He regards the species to which they belong as new, and names it *Camelus alutensis*.

WE learn from *Nature* that at a meeting of the Essex Field Club, on July 21st, a discussion was held for the consideration of practical methods for the protection of our native fauna and flora from the destruction and actual extermination which now threaten many interesting species. Mr. C. G. Barrett (Hon. Secretary to the Committee of the Entomological Society for the Protection of Insects in danger of extermination) opened the subject by a short address on 'Insect protection; its necessity, means and objects.' Mr. J. E. Harting spoke with respect to birds and mammals; Professor Boulger referred to the wholesale collecting which was exterminating many rare plants; and Professor Meldola urged that children should be taught to respect the sacredness of life. The following resolution of Professor Boulger's was adopted unanimously, and the Club resolved to assist the scheme of the Entomological Society in every possible way: "That in view of the danger of extermination threatening many beautiful, rare and interesting plants, all lovers of nature should do their best to avoid this danger: (*a*) By abstaining from wholesale collecting, collecting for merely individual private collections, needless rooting-up of specimens, attempting to cultivate wild specimens of refractory species, and purchasing such wild specimens from itinerant or other dealers; (*b*) by endeavoring to persuade others, especially school children, cottage gardeners, and dwellers in large towns, to a similar abstention."

A REUTER telegram from Stockholm says that in a letter to the *Aftonblad*, Dr. Nils Ekholm, who accompanied Herr Andrée to Spitzbergen last year with the intention of taking part in his aërial voyage, offers some remarks on the prospect of the expedition based on the full details now received of Herr Andrée's ascent. Herr Ekholm declined to go this year because he considered that the impermeability of the balloon was unsatisfactory. In his letter he points out that from the day the balloon was fully inflated it lost 51 cubic meters of gas every 24 hours, representing a diminution in

carrying capacity of 56 kilogrammes per day. This, he says, shows that the imperviousness of the balloon had not been essentially increased since last year. Besides this daily escape, various circumstances led to a certain loss of gas in the ascent itself, necessitating a corresponding sacrifice of ballast. After making allowance for these losses of gas, and taking into consideration the fact that in the ascent part of the drag-ropes were lost and that the balloon at once rose to a height of 15,000 ft. to 25,000 ft., which was more than had been reckoned upon, Dr. Ekholm comes to the following conclusions: The longest time for which the balloon would remain in the air would be from 22 to 24 days, and less if mountains exceeding the height attained at the start had to be crossed. As the duration of the projected voyage may be estimated in ordinary conditions as regards wind at 24 days, remarkable good fortune would be necessary for success.

LIEUTENANTS VANNUTELLI AND CATERNI, the surviving officers of the Bottego expedition, have sent in a report to the Italian Geographical Society, which is summarized in a dispatch to the London *Times*. The expedition set out on February 2, 1895, from Sancurar, and after touching Vollamo visited Pogadesen (?), and arrived on June 1, 1896, at Omo. In consequence of continuous fighting with the warlike tribes inhabiting these regions, the members of the expedition were obliged to spend the months of July and August, 1896, on the shores of Lake Rudolf. At this point Dr. Sacchi left the expedition, taking with him some valuable mineralogical and zoological collections and proceeded to Lugh. The main expedition proceeded up to the Ethiopian plateau, stopping at Sajo, whence a letter was forwarded to the Galla chief Degiasmac. In consequence of the friendly assurances given by the latter, the expedition continued its forward march, arriving on March 16th of the present year in the neighborhood of Gabo. The chief, notwithstanding his friendly assurances, behaved treacherously and caused the party to be surrounded, so that they had no course left but to attempt to cut their way out. Of the 86 members of the expedition, 66, including its leader, were killed, the survivors being taken prisoners and having many hardships to endure. On June 6th last the captives were sent by order of the Emperor Menelik to Shoa, where they arrived on June 22d and were handed over to Major Nerazzini. The documents belonging to the expedition were saved, only the collections intrusted to Dr. Sacchi having been lost. It is thought probable that the latter was killed.

THE British Society of Inspectors of Weights and Measures recently held its annual general meeting in London. The total membership of the Society is now upwards of three hundred, and sixty cities and towns were represented at the meeting. Sir Henry Roscoe, the Vice-President, made an address on the subject of the metric system of weights and measures. He reminded the members that he was the Chairman of the Select Committee of the House of Commons, appointed two sessions ago, to report on the question of how far it was desirable to alter our system of weights and measures and adopt the metric system, which, he said, was almost universal throughout civilized, and to some extent uncivilized countries. He joined with the members of the Society in the hope that the bill would soon pass into law. It did not do all that they had hoped for, but they must, he thought, accept it as an installment. Sir John Hutton reported that of one and three-quarter million scales examined in London, one-third had proved defective. The members of the Society visited the Victorian Exhibition of the Crystal Palace, where a Section of Weights and Measures had been organized by the Society, and subsequently went to Paris to view the standards and appliances of the French government at the Bureau central.

THE Berlin Town Council has decided to appoint a municipal 'hydrologist' for the hygienic supervision of the water supply of the city.

SIGNOR CESARESCO writes to the London *Times* asking for the suppression of the export of quails and small birds from Italy to England. It is said that millions are sent to England from Egypt and from the south of Italy, part of which are caught in defiance of such protective laws as exist, while the rest are netted in the spring and autumn and are kept in more or less

misery till the time comes for their despatch to meet the requirements of the London season, which coincides with the natural nesting time. The French government for some years prohibited the transit of quails through France in the close season, but as this simply led to their being sent through Germany and Belgium the prohibition has been removed, notwithstanding the protests of the Union des Sociétés des Chasses. Millions of small birds called 'larks,' though they include every variety, and especially robbins, killed largely during the breeding season, are also annually exported to England, and it is feared that they will be entirely exterminated in Italy.

UNIVERSITY AND EDUCATIONAL NEWS.

A LARGE majority of the professors of Brown University have signed an open letter addressing to the corporation a protest against attempting to curtail the freedom of speech of the President. The letter gives a straightforward expression to the views which university professors should unite in maintaining and removes from Brown University the stigma put by the corporation in claiming that they can control the freedom of speech of its faculty. President Andrews, however, in accepting the presidency of a magazine 'university' confuses the friends of academic freedom.

THE London University Commission bill has been postponed by the government until next year.

IT is reported in the daily papers that Mr. Washington Corrington, of Peoria, Ill., now eighty-five years old, has appointed trustees to have control of his property, to be used after his death to found a university at Peoria. His property is estimated at over $1,000,000.

THE Bradley Polytechnic Institute, of Peoria, will be dedicated on October 8th, the principal address being made by the Secretary of the Treasury, Hon. Lyman J. Gage.

THE trustees of the University of Illinois have decided to admit women to the College of Physicians, Chicago.

AT a recent meeting of the Council of the University of Paris it was resolved that, as soon as financial resources permitted, the following courses should be added: Experimental physiology, objective psychology and astronomical physics, and additional courses in paleontology and histology.

IT is intended that the name of Croom Robertson, late Grote professor in University College, London, to whom psychology in England is greatly indebted, shall be connected in some way with the new psychological laboratory established at University College. The principal contributors to the fund are Mr. Haldane, Q. C., Mr. A. J. Balfour, Professor H. Sidgwick, Mr. F. Galton, Dr. Savage, Sir John Lubbock and Mr. Shadworth Hodgson.

THE London *Times* reports that at Dewsbury, after the funeral of Dr. Hinchliffe, it was announced that the deceased, after providing for his housekeeper and servants, had bequeathed property and shares, with about £50,000, toward higher education, but the purposes of the bequest are not stated.

DR. H. V. NEAL, Harvard University, has been elected professor of biology at Knox College, Galesburg, Ill.

M. IZOULET has been appointed to the newly established professorship of social philosophy in the Collège de France.

MR. W. W. WATTS, Assistant Geologist at the British Geological Survey, has been appointed assistant professor of geology at Mason College, Birmingham.

DR. HERMANN THOMES, docent in pharmaceutical chemistry in the University of Berlin, has been promoted to a professorship. Professor George Ruge, of Amsterdam, has been appointed professor of anatomy and director of the Anatomical Institute at Zurich. Dr. Ossan, associate professor of mineralogy at Heidelberg, has been called to a chair in the School of Chemistry at Mühlhausen.

DISCUSSION AND CORRESPONDENCE.

THE ANTECEDENT COLORADO.

TO THE EDITOR OF SCIENCE: In addition to the doubts brought forward by Davis (SCIENCE,

April 23, 1897) and Emmons (SCIENCE, July 2d), as to the antecedent origin of the Green river in its passage through the Uinta mountains, I would suggest an independent and confirmatory argument for the consequent origin of the Green-Colorado in its passage across the plateaus of the Grand Canyon region, where it has been regarded as antecedent by Powell and Dutton. My argument is based on the curvature of the river and especially on its meanders. The meanders are surprising in themselves from the steepness of the river and their deep incision; yet more surprising is the location of strong meander reaches just up stream from structural displacements. It is the latter relation that I wish to point out.

In general, a river meanders when its declivity is low. The Mississippi below Memphis falls less than five inches to the mile and has a typical meandering course (See Table of Meanders). Yet the Colorado, falling more than seven feet per mile in the Canyon region, has stretches of even greater sinuosity and the distribution of these winding reaches suggests that the river is not antecedent, but dependent on the dislocations for its path.

The following table shows the rate of meander for measured stretches of the river, the rate being expressed in miles of actual stream to 100 miles along a mean course traced evenly through the meanders, without departing more than a mile from the water at any point. In the first column is the name given by Powell to the stretches of river, in the second the miles of mean course, in the third the actual course, while the fourth contains the rate of meander:

1	2	3	4
Desolation and Gray Canyons—Uinta R. to Book Cliffs, ...	76	113	149
Gunnison's Valley—to San Rafael R	30	35	117
Labyrinth Canyon—to Grand R . .	51	93	182
Cataract Canyon — to N 37°37′, W 110°38′.	77	81	105
Glen Canyon and above—to Paria R	88	139	158
Marble and Grand Canyons — to Grand Wash	259½	280	108
Thence to California boundary. . .	139	145	104
Mississippi — Memphis to Baton Rouge			155

The 139 miles of strong meander above the Paria River bring the Colorado down to the East Kaibab monocline, where the course turns to the south to avoid the uplifted Kaibab plateau, just as the Green turns east on reaching the Uintas. This is best seen on the United States Relief Map, where the darker color is within the river's elbow at the Uinta and against the Kaibab.

At the monocline the river is deviated. In Glen Canyon above the monocline the meandering is greater than the Mississippi's. Below the meandering is reduced to a minimum.

The conclusion is irresistible that the Kaibab uplift introduced a local baselevel (Powell's phrase) that compelled the river to meander on a flat open course until the obstacle gave passage to one side.

Less than a hundred miles further north in the Cataract Canyon, near the junction of the Green and Grand, the river's course is straight (meander rate, 105). Next above this is the very sinuous Labyrinth Canyon (rate, 182). The geological map here shows a dome with Permian and Carboniferous brought to the surface, a part probably of the San Rafael disturbance. Through the dome the course is in the straight Cataract Canyon; the Labyrinth Canyon is the northern approach.

Is the analogy here to the Kaibab and Glen Canyon casual?

Gunnison's valley is instructive. It has little meander and no uplift. Dutton reports it to be the only open valley on the river besides Brown's Park, and attributes this character to the softness of strata that weather back too rapidly to stand in canyon walls. In this case surface meanders would be lost here, as the the valley would straighten as it widened under erosion.

To the north the meandering is again great. At the time the river took to meandering it may well have had such a course from the Uintas to the dome, preserved to us where the rocks were hard and the river now runs in canyons, but lost in the softer strata. North of the Uintas I have no map, but this stretch of Gunnison's suggests that meanders would not be preserved in the soft rocks of the Bad Lands.

In this connection I would call attention to a striking feature of the Grand Canyon faults, as described by Dutton in his monograph. He says the ends of the down-thrown strata are commonly turned *down* in this region, the beds on the other side coming undisturbed to the fault. This is specifically described for the West Kaibab and Hurricane faults, both with up-throw to east.

The phenomenon of the down-turned edges is puzzling, but it might result from the following history. All the steps assumed to follow in succession are found in the region to-day:

1. Western beds flexed up, giving a western high level passing through a monocline to an eastern low level.

2. Flexure becomes a fault at the foot (east end) of the monocline, giving western high level passing down a monocline to an east-facing fault cliff, below which lie the horizontal beds of the undisturbed side.

3. Reversal of fault, giving upthrow on east and the structure existing to-day—low level on west passing to a west-facing fault cliff by a down-turn (monocline perhaps partly obliterated by friction during the reversal).

In confirmation is the fact that both faults are greatest in the north and steadily diminish southward, the Hurricane having at the river less than a sixth of its northern value, while the West Kaibab disappears just where it crosses the chasm. Dutton thinks it reappears to the south of the canyon, but *reversed*, giving an east-facing cliff. So if the observation of Dutton is good, reversal of fault has occurred in one case and there is a suggestion of it in the other. Now the significance of this fault history is that the river seems conscious of something of the sort. It turns south on the second V of the Grand Canyon at the Hurricane fault, as if to avoid the early western uplift, now recorded only in the down-turned strata-ends; while at the Kaibal the reversal-point has been selected by the river to return northward from the deviation about the uplift here. The peculiar grouping of meanders is readily seen on the map, as also the relation of bends in the river to the displacements at the Uinta, junction of Grand and Green, Kaibab (East and West), and Hurricane.

In explaining these latter events as represented in effect on the present river, I have founded my suggestion on that simple and diagrammatic character that Powell and Dutton have described in this region.

Are not these additional grounds for questioning the Colorado's antecedence?

AMPHIBIA OR BATRACHIA.

To the Editor of Science: As a teacher of zoology, but without claim to expert authority upon taxonomic points, I read the article of Dr. Baur under the above title (Science, July 30, 1897, 170–174), with the hope and expectation of being able to decide which name to employ hereafter. I regret to confess myself still unconvinced. Dr. Baur shows that the French word *Batraciens* was applied to the frogs, toads and salamanders by Brogniart in 1799, and that the Latin forms *Batrachii* and *Batrachia* were not introduced until 1804 and 1807, by Latreille and Gravenhorst respectively. But does not Dr. Baur lay undue stress upon the distinction between the French and the Latin form. *Batraciens* is not (like *crapaud*, etc.) a vernacular word; it is the French form, or Galloparonym, of the Latin *Batrachia*, and the employment of the former would seem to constructively sanction the use of the latter. In anatomy the employment of either of the national forms, *hippocamp*, *Hippokamp*, *hippocampe*, or *hippocampo*, would be tantamount to the introduction of the international form, *hippocampus*. The principle involved in both cases has been formulated by me in two passages in my 'Neural Terms, International and National (*Jour. Comp. Neurology*, VI., 274, 329), as follows: "The introduction of any derivative, oblique case, or national paronym, practically renders the introducer responsible for the actual or potential Latin antecedent of such words, in accordance with the usual rules of derivation and paronymy." I trust the discussion may continue until all doubts are removed. The case is the more urgent in view of the confusion of students in finding not merely that *Amphibia* and *Batrachia* are synonyms for the entire class,

but also that in Huxley's writings the latter is applied to an ordinal subdivision of the former.

BURT G. WILDER.

SCIENTIFIC LITERATURE.

Report on the Valley Regions of Alabama. By HENRY MCCALLEY, Assistant State Geologist. Part I., on the Tennessee Valley Region, pp. 436. Part II., on the Coosa Valley Regions, pp. 862. Geological Survey of Alabama, Montgomery, 1896–97.

The aim of this report is to give a complete account of the geology and mineral resources of that part of Alabama which is occupied by known Paleozoic formations. This includes approximately the northern third of the State, with an area of about 18,000 square miles. It is limited on the southeast by the metamorphic series of undetermined age and on the southwest by the unconformable post-Paleozoic formations. The term 'valley regions' in the title is somewhat misleading, since all the mountains of Alabama, such as they are, are included in the region described and are as fully treated as the adjacent valleys. Except to one already familiar with the topographic features of the State, the title conveys no idea of location whatever.

The region outlined above is about equally divided between the Tennessee and Coosa drainage basins, and this division is a natural one from geologic and economic points of view. It is, therefore, taken as the basis for subdividing the report into two parts which treat respectively of the Tennessee and Coosa Valley regions. Each part is again subdivided into two sections. In the first is given a general account of the topography, geology and mineral resources, and in the second each county is described in detail. This method of treatment is, perhaps, necessary where the county is the all-important unit in the political and social organization, but its defects are serious as seen in the present case. It involves endless repetition and distributes through a volume details which should be in a compact body. Thus there are 275 more or less extended but entirely distinct references to the limonite deposits, containing sufficient observations for an exhaustive monograph on the subject if brought together and properly arranged. Yet one seeks in vain for any systematic classification of the deposits or a statement of their essential characteristics.

In reading the report one is continually hampered by the lack of maps. It is true the State geological map, published in 1894, is referred to, but its scale is entirely too small for representing details of structure, and in numerous respects it does not correspond with the statements in the report. The crudest sort of sketch maps would be of the greatest assistance to an understanding of the complicated structural relations found in parts of this region. In fact, no amount of verbal description, even from a master of English, can supply their place, and the present case is hopeless for reasons which the following quoted sentence will readily suggest: "The northeast end of the belt, just to the northwest of the Terrapin or Ladiga Mountains, or the portion of that belt within this county, is a portion of the counterpart of the belt last described, or is a portion of the southeast rim of the badly faulted, broad, broken, unsymmetrical synclinal of which the belt last described is the major part of the northwest rim." The reader cannot rid himself of the suspicion that among other reasons for the absence of maps and diagrams is the lack, on the author's part, of a sufficiently clear conception of the structure for their preparation.

In the descriptions of topographic features the principles of modern geography or physiography are entirely ignored. Hence there is a vagueness and uncertainty about the descriptions which might have been excusable twenty years ago, but for which no excuse can be found at the present time. It borders on the absurd to speak of 'high rugged mountains with lofty peaks' in Alabama, where the greatest relief is barely 2,000 feet above the sea-level.

By far the most valuable portion of the report is found in the detailed county descriptions, especially those of mineral deposits. Here is a vast mass of facts, poorly digested and arranged, it is true, but given in such a way that they will be of great service in the economic development of the region. All locations are given by land numbers, so that, while they convey little meaning to the general reader, they are in the best possible form for use by the prospector upon the ground.

AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

*A CHAPTER IN THE HISTORY OF MATHEMATICS.**

ON the 10th of March, 1897, a hundred years after its original presentation, the Royal Academy of Sciences and Letters of Denmark published a French translation of a memoir by Caspar Wessel, entitled *Om Direktionens analytiske Betegning, et Forsög, anvendt fornemmelig til plane og sphaeriske Polygoners Oplösning*, or an Essay on the Analytic Representation of Direction, with Applications in Particular to the Determination of Plane and Spherical Polygons.

This paper, which deals with the geometric representation of imaginary quantities; which was read and printed several years before the famous essay of Argand and contains fully as exact a treatment of the subject, lay buried for nearly a century until attention was again drawn to it in 1895 by a thesis of S. D. Christensen upon the development of mathematics in Denmark and Norway in the eighteenth century.

Inasmuch as this memoir of Wessel's is still comparatively unknown, I have thought that it would not be uninteresting at this time to present a sketch of the development of the geometric treatment of the imaginary, particularly in the latter part of the eighteenth century and the first part of the nineteenth.

We find the square root of a negative quantity appearing for the first time in the *Stereometria* of Heron of Alexandria, 100 B. C. After having given a correct formula for the determination of the volume of a frustum of a pyramid with square base and applied it successfully to the case where the side of

*Address by the Vice-President before Section A, Mathematics and Astronomy.

the lower base is 10, of the upper 2, and the edge 9, the author endeavors to solve the problem when the side of the lower base is 28, of the upper 4, and the edge 15. Instead of the square root of 81–144 required by the formula, he takes the square root of 144–81 and calls it equal to 8 less $\frac{1}{16}$, *i. e.*, he replaces $\sqrt{-1}$ by 1, and fails to observe that the problem as stated is impossible. Whether this mistake was due to Heron or to the ignorance of some copyist cannot be determined.

In the solution of the problem to find a right angled triangle whose perimeter is 12 and area 7, Diophantus, in his *Arithmetica*, 300 A. D., reaches the equation $336x^2+24=172x$ and says that the equation cannot be solved unless the square of the half coefficient of x diminished by the product of 24 and the coefficient of x^2 is a square. No notice is taken of the fact that the value of x in this equation actually involves the square root of a negative quantity.

Bhaskara, born 1114 A. D., in his chapter *Vija Ganita*, was able to go a step further. He gave the rule :

> The square of a positive number as also of a negative number is positive and the square root of a positive number is twofold, positive and negative. There is no square root of a negative number, for this is not a square.

The first mathematician who had the courage actually to use the square root of a negative number in computation was Cardano. At an earlier period he had declared such a quantity to be wholly impossible, but in the *Ars Magna*, 1545, he discusses the problem of dividing 10 into two parts whose product shall be 40 and obtains the values $5+\sqrt{-15}$, $5-\sqrt{-15}$. These he verifies by multiplication. Such quantities he calls sophistic, since it is not permissible to operate with them as with pure negative numbers or others, nor to assign them a meaning.

Bombelli, in his *Algebra*, 1572, gives a number of rules for the use of such quantities as $a+b\sqrt{-1}$, but makes no endeavor to explain their character.

Girard knew that every equation has as many roots as its degree indicates and consequently recognized the existence of imaginary roots. In his *Invention nouvelle en l' algèbre*, 1629, while discussing the roots of the equation $x^4-4x+3=0$ he asks what purpose is subserved by such roots as $-1+\sqrt{-2}$ and $-1-\sqrt{-2}$ and says that they show the generality of the law of formation of the coefficients and are useful of themselves.

Descartes, in his *Geometria*, 1637, gives us no new ideas upon the subject, but is the first to apply the terms real and imaginary by way of contrast to the roots of an equation.

Wallis, in his *Treatise of Algebra*, 1685, leads the van in his endeavor to give a geometric interpretation to the square root of a negative number. In chapter LXVI we read :

> These *Imaginary* Quantities (as they are commonly called) arising from the *Supposed* Root of a Negative Square (when they happen,) are reputed to imply that the Case proposed is Impossible.
>
> And so indeed it is, as to the first and strict notion of what is proposed. For it is not possible that any Number (Negative or Affirmative) Multiplied into itself can produce (for instance) —4. Since that Like Signs (whether + or —) will produce + ; and therefore not —4.
>
> But it is also Impossible that any Quantity (though not a Supposed Square) can be *Negative*. Since that it is not possible that any *Magnitude can be Less than Nothing* or any *Number Fewer than None.*
>
> Yet is not that Supposition (of Negative Quantities,) either Unuseful or Absurd ; when rightly understood. And though, as to the bare Algebraick Notation, it import a Quantity less than nothing. Yet, when it comes to a Physical Application, it denotes as Real a Quantity as if the Sign were +; but to be interpreted in a contrary sense.

He illustrates this by distances measured forward and backward upon a straight line in the usual way, and continues :

> Now what is admitted in Lines must, on the same Reason, be allowed in Plains also.

Having thus justified the existence of negative planes, he goes on:

But now (supposing this Negative Plain, —1600 Perches, to be in the form of a Square;) must not this Supposed Square be supposed to have a Side? And if so, what shall this Side be?

We cannot say it is 40, nor that it is —40 * *

But thus rather that it is $\sqrt{-1600}$, or * * 10 $\sqrt{-16}$, or 20 $\sqrt{-4}$, or 40 $\sqrt{-1}$.

Where $\sqrt{}$ implies a Mean Proportional between a Positive and a Negative Quantity. For like as $\sqrt{bc}$ signifies a Mean Proportional between $+b$ and $+c$; or between $-b$ and $-c$; * * So doth $\sqrt{-bc}$ signify a Mean Proportional between $+b$ and $-c$, or between $-b$ and $+c$.

In chapter LXVII Wallis gives a geometric exemplification of a mean proportional, interpreting $\sqrt{bc}$ as a sine in a circle whose diameter $=b+c$, and $\sqrt{-bc}$ as a tangent in a circle whose diameter $=-b+c$. He then finds the base of a triangle when the two sides and the angle opposite, and hence the altitude, are given. Assuming $AP=20$, $PB=15$, and the altitude $PC=12$, by the use of the triangle BCP, right-angled at C, he obtains two values for the base AB. Then taking $AP=20$, $PB=12$, and the altitude $PC=15$, he finds imaginary values for the base.

These he interprets by saying:

This Impossibility in *Algebra* argues an Impossibility of the case proposed in Geometry; and that the Point B cannot be had, (as supposed,) in the Line AC, however produced (forward or backward,) from A.

Yet there are Two Points designed (out of that Line, but) in the same Plain; to either of which, if we draw the Lines AB, BP, we have a Triangle; whose Sides, AP, PB, are such as were required: And the Angle PAC, and Altitude PC, (above AC, though not above AB,) such as was proposed:

In this case he takes the triangle BCP to be right angled at B. Further:

And (in the Figure,) though not the Two Lines themselves, AB, AB, (as in the First case, where they lay in the Line AC:) yet the Ground-Lines on which they stand, $A\beta$, $A\beta$, are equal to the Double of AC: That is, if to either of those AB, we join Ba, equal to the other of them, and with the same Declivity; ACa (the distance of Aa) will be a Straight Line equal to the double of AC; as is ACa in the First case.

The greatest difference is this; that in the first Case, the Points B, B, lying in the Line AC, the Lines AB, AB, are the same with their Ground-Lines, but not so in this last case where B, B are so raised above β β (the respective Points in their Ground-Lines, over which they stand), as to make the case feasible; (that is, so much as is the versed sine of CB to the Diameter PC:) But in both ACa (the Ground-Line of ABa) is equal to the Double of AC.

So that, whereas in case of Negative Roots, we are to say, The Point B cannot be found, so as is supposed in AC Forward, but Backward from A it may in the same Line: We must here say, in case of a Negative Square, the Point B cannot be found so as was supposed, in the Line AC; but Above that Line it may in the same Plain. This I have the more largely insisted upon, because the Notion (I think) is new; and this, the plainest Declaration that at present I can think of, to explicate what we commonly call the *Imaginary Roots* of Quadratic Equations. For such are these.

From these extracts it is evident that Wallis possessed, at least in germ, some elements of the modern methods of addition and subtraction of directed lines.

For the next hundred years no advance of importance was made. Euler, for example, makes large use of the imaginary, but in his *Algebra*, 1770, he observes:

All such expressions as $\sqrt{-1}$, $\sqrt{-2}$, etc., are consequently impossible or imaginary numbers, since they represent roots of negative quantities; and of such numbers we may truly assert that they are neither nothing, nor greater than nothing, nor less than nothing, which necessarily constitutes them imaginary or impossible.

On the 10th of March, 1797, a surveyor named Wessel presented to the Royal Academy of Sciences and Letters of Denmark a memoir 'On the Analytic Representation of Direction,' which was printed in 1798 and appeared in Vol. V, of the Memoirs of the Academy in 1799.

Caspar Wessel was born June 8, 1745, at Jonsrud, in Norway, where his father was a pastor. Though one of thirteen children, he had a good education, for in 1757 he entered the high school at Christiania and

in 1763 went to Copenhagen to pursue further studies. In 1764 he was engaged by the Academy of Sciences as an assistant in the triangulation and preparation of a map of Denmark. Till 1805 he remained in the continuous employ of the Academy as surveyor. Wessel was highly esteemed by his contemporaries, and for some special work done after leaving the service of the Academy he received the Academy's silver medal and a full set of its memoirs. In 1819, when many of its maps were declared out of date, the trigonometric determinations of Wessel were made a special exception. In 1778 he passed an examination in Roman law. In 1815 he was made a Knight of the Danebrog. He died in 1818.

While Wessel was always well spoken of as a surveyor, he was never mentioned as a mathematician. Still the fact that his paper was the first to be accepted by the Academy from one not a member argues in his favor. This acceptance was due to Tetens, Councillor of State, to whom the MS. had been shown and whose assistance in improving it was acknowledged. In the History of the Academy of Sciences of Denmark published in 1843 Professor Jürgensen classes Wessel with others in the statement, "The treatises of the other mathematicians are monographs of no considerable scientific value," or "They are too special to be discussed more at length."

In the introduction to his memoir Wessel says:

The present essay has for its object to determine how to express segments of straight lines when we wish by means of a unique equation between a single unknown segment and other given segments to find an expression representing at once the length and direction of the unknown segment.

To be able to answer this question I shall employ two considerations which seem to me evident. In the first place, the variation of direction which may be produced by algebraic operations ought also to be represented by their symbols. In the second place we submit direction to algebra only by making its variation depend upon algebraic operations. Now according to the ordinary conception we can transform it by these operations only into the opposite direction, that is, from positive into negative and reciprocally. It follows that these two directions only would be susceptible of an analytic representation adapted to the usual conception and that the solution of the problem would be impossible for other directions. It is probably for this reason that nobody has given attention to this subject. Doubtless nobody has felt at liberty to change the definition of these operations once adopted. To this there is no objection so long as the definition is applied to ordinary quantities; but there are special cases where the peculiar nature of the quantities seems to invite us to give particular definitions to the operations. Then if we find these definitions advantageous it seems to me that we ought not to reject them. For in passing from arithmetic to geometric analysis, that is to say, from operations relative to abstract numbers to operations upon segments of a straight line, we shall have to consider quantities which may have to one another not only the same relations as abstract numbers, but also a great number of new relations. Let us try then to generalize the signification of our operations; let us not restrict ourselves, as has been done hitherto, to the employment of segments of a straight line in the same or opposite senses, but extend a little the notion of the way in which they are applied not only to the same cases as heretofore, but to an infinite number of other cases. If at the same time that we take this liberty we have respect to the ordinary rules of operations we in no way contravene the ordinary theory of numbers, but we merely develop it, we accommodate ourselves to the nature of the quantities and observe the general rule which requires us to render a difficult theory little by little more easy to comprehend. It is not then absurd to demand that in geometry operations be taken in a broader sense than in arithmetic. We shall admit without difficulty that it will be possible to vary the direction of segments in an infinite number of ways. Precisely by this means (as we shall show later) we succeed not only in avoiding all impossible operations and in explaining the paradox that it is necessary sometimes to resort to the impossible to obtain the possible, but we also succeed in expressing the direction of line-segments situated in the same plane quite as analytically as their length, without the memoir being embarrassed by new symbols or new rules. Now it must be agreed that the general demonstration of geometric theorems often becomes easier when we express direction in an analytic manner and submit it to the rules of algebraic operations than when we are compelled to represent it by figures which are applicable only to particular cases.

For these reasons I have proposed to myself:

1° to give the rules of operations of this nature;

2° to show by examples the application to cases where the segments are found in the same plane;

3° to determine by a new method not algebraic the direction of segments situated in different planes;

4° to deduce the general solution of plane and spherical polygons;

5° to deduce in the same way the known formulæ of spherical trignometry.

This, in brief, is an outline of the present memoir. I was led to write it by my desire to find a method which would enable me to avoid impossible operations; having discovered it I have made use of it to convince myself of the generality of certain known formulæ.

How well the author succeeds in carrying out his plan is shown by the memoir itself. Wessel says:

The addition of two segments is effected in the following manner: we combine them by drawing the one from the point where the other terminates; then we join by a new segment the two ends of the broken line thus determined.

He extends the definition to more than two segments and affirms:

In the addition of segments, the order of terms is arbitrary and the sum always remains the same.

His definition of the product of two segments is especially noteworthy:

The product of the two line-segments ought in every respect to be formed with one of the factors in the same way as the other factor is formed, with the positive or absolute segment taken equal to unity; that is to say:

1° The factors ought to have such a direction that they can be placed in the same plane as the positive unit;

2° As to length the product should be to one of the factors as the other is to the unit;

3° As to the direction of the product, if we draw from the same origin the positive unit, the factors and the product, the latter ought to be in the plane of the unit and the factors, and ought to deviate from one of the factors by as many degrees and in the same sense as the other deviates from the unit so that the angle of direction of the product or its deviation with respect to the positive unit is equal to the sum of the angles of direction of the factors.

Let us designate by $+1$ the positive rectilinear unit, by $+\varepsilon$ another unit perpendicular to the first and having the same origin; then the angle of direction of $+1$ will be equal to $0°$, that of -1 to $180°$, that of $+\varepsilon$ to $90°$ and that of $-\varepsilon$ to $-90°$ or to $270°$; and according to the rule that the angle of direction of the product is equal to the sum of the angles of the factors, we shall have: $(+1).\ (+1)=+1$, $(+1).\ (-1)=-1$, $(-1)\cdot(-1)=+1$, $(+1)\cdot(-\varepsilon)=-\varepsilon$, $(-1)\cdot(+\varepsilon)=-\varepsilon$, $(-1)\cdot(-\varepsilon)=+\varepsilon$, $(+\varepsilon)\cdot(+\varepsilon)=-1$, $(+\varepsilon)\cdot(-\varepsilon)=+1$, $(-\varepsilon)\cdot(-\varepsilon)=-1$. Hence it follows that ε is equal to $\sqrt{-1}$ and that the deviation of the product is determined so that we violate none of the ordinary rules of operation.

It is interesting to note that while Wessel makes the addition and multiplication of directed lines a matter of definition, Argand, in his famous memoir of 1806, *Essai sur une manière de représenter les quantités imaginaires dans les constructions géométriques*, says: "Inasmuch as these principles depend upon inductions which are not securely established, they cannot as yet be considered as other than hypotheses whose acceptance or rejection should depend upon either the consequences which they entail or a more rigorous logic," although in his last contribution to the *Annales de Gergonne* he grants that this difficulty will vanish if with M. Français we define what is meant by a ratio of magnitude and position between two lines.

After explaining that if v represents any angle, and $\sin v$ a segment equal in length to the sine, positive when the measuring arc terminates in the first semicircumference and negative when it terminates in the second, $\varepsilon \sin v$ will express the sine of the angle v in direction and magnitude, Wessel shows that any radius making the angle v with the positive unit will equal $\cos v+\varepsilon \sin v$. In the multiplication of two radii $\cos v+\varepsilon \sin v$, $\cos u+\varepsilon \sin u$, he establishes the distributive law by reference to the formulæ,

$$\sin (v+u) = \sin v \cos u + \cos v \sin u,$$
$$\cos (v+u) = \cos v \cos u - \sin v \sin u,$$

in contrast to Argand, who assumes the distributive law and then derives the trigonometric formulæ.

A statement in this connection is noteworthy:

But if we have to multiply line segments which are not both in the plane passing through the absolute unit we cannot apply the preceding rule. For this reason I do not consider the multiplication of such segments.

The treatment of division follows in a natural manner, and it is proved that indirect quantities share with direct quantities the property that if the dividend is a sum we obtain by dividing each term of the sum by the divisor several quotients whose sum is the quotient sought.

Then comes a discussion of powers and roots establishing the fact that $(\cos v + \varepsilon \sin v)^{\frac{1}{m}}$ has m different values and only m. In the next paragraph Wessel shows that the m^{th} power of a line-segment may be put in the form $e^{ma+mb\sqrt{-1}}$, where e^{ma} represents the length and mb the angle of direction, and that thus we have a new method of representing the direction of line-segments in the same plane by the aid of natural logarithms. This last is not again referred to, but it is readily seen that Wessel was in possession of all three of the present methods of representing the complex number,

$a+b\sqrt{-1}$, $r(\cos\varphi+\sqrt{-1}\sin\varphi)$ and $re^{\phi\sqrt{-1}}$.

At the close of this section the author remarks:

At another time, with the permission of the Academy, I will present the complete proofs of these theorems. Having given an account of the way in which we must, in my judgment, understand the sum, the product, the quotient and power of line segments, I shall restrict myself to a few applications of the method.

The first application is to a demonstration of Cotes's theorem in which the fundamental theorem of algebraic equations is assumed as previously established. The second is to the resolution of plane polygons. In this certain characteristic notations occur. The first side of the quadrilateral considered is taken equal to the absolute unit; the sides in order beginning with the first are designated by the even numbers II, IV, VI, VIII, while I, III, V, VII, represent their deviations (in degrees) each with respect to the preceding side prolonged, regarding these deviations as positive or negative according as they have the same sense as the diurnal motion of the sun or the opposite; I′, III′, V′, VII′ denote the expressions $\cos \mathrm{I} + \varepsilon \sin \mathrm{I}$, etc., while $\mathrm{I}^{-\prime}$, $\mathrm{III}^{-\prime}$, $\mathrm{V}^{-\prime}$, $\mathrm{VII}^{-\prime}$ denote the expressions $\cos(-\mathrm{I}) + \varepsilon \sin(-\mathrm{I})$ or $\cos \mathrm{I} - \varepsilon \sin \mathrm{I}$, etc.

The author then deduces the two formulæ,

$$\mathrm{II} + \mathrm{IV} \cdot \mathrm{III}' + \mathrm{VI} \cdot \mathrm{III}' \cdot \mathrm{V}' + \mathrm{VIII} \cdot \mathrm{III}' \cdot \mathrm{V}' \cdot \mathrm{VII}' = 0,$$

$$\mathrm{II} \cdot \mathrm{III}' \cdot \mathrm{V}' \cdot \mathrm{VII}' + \mathrm{IV} \cdot \mathrm{V}' \cdot \mathrm{VII}' + \mathrm{VI} \cdot \mathrm{VII}' + \mathrm{VIII} = 0,$$

and proves that two equations of this form will suffice for the solution of any polygon in which the only unknown parts are three angles, or two angles and a side, or an angle and two sides.

Wessel next attacks the problem of representing the direction of any line segment in space by taking it as the radius, r, of a sphere. Assuming three perpendicular radii as axes and denoting positive unit lengths upon these, to the left by 1, forward by ε and upward by η respectively, where $\varepsilon^2 = -1$, and $\eta^2 = -1$, he concludes that a radius whose extremity has for coordinates $x, \eta y, \varepsilon z$ will be properly designated by $x + \eta y + \varepsilon z$. Defining the plane of r and εr as the horizontal plane and that of r and ηr as the vertical plane, he examines the effect of moving the extremity through an arc of I degrees parallel to the horizontal plane and obtains for $x + \eta y + \varepsilon z$ the new value,

$$\eta y + (x + \varepsilon z)(\cos \mathrm{I} + \varepsilon \sin \mathrm{I}) = \eta y + x \cos \mathrm{I} - z \sin \mathrm{I} + \varepsilon x \sin \mathrm{I} + \varepsilon z \cos \mathrm{I},$$

in which the term ηy remains unchanged. This operation he indicates by the use of

the sign ,, as $(x + \eta y + \varepsilon z)$,, $(\cos \mathrm{I} + \varepsilon \sin \mathrm{I})$ and says that it has only imperfectly the signification of a sign of multiplication, for the operation leaves unchanged that one of the segments occurring in the multiplicand which is outside of the plane corresponding to the rotation indicated by the multiplier. He calls attention to the fact that the factors must be used in order from left to right. Similarly when the extremity of the radius moves through an arc of II degrees parallel to the vertical plane we have

$$(x + \eta y + \varepsilon z) ,, (\cos \mathrm{II} + \eta \sin \mathrm{II}) = \varepsilon z + x \cos \mathrm{II} - y \sin \mathrm{II} + \eta x \sin \mathrm{II} + \eta y \cos \mathrm{II}.$$

It follows at once that

$$(x + \eta y + \varepsilon z) ,, (\cos \mathrm{I} + \varepsilon \sin \mathrm{I}) ,, (\cos \mathrm{III} + \varepsilon \sin \mathrm{III}) = (x + \eta y + \varepsilon z) ,, (\cos (\mathrm{I} + \mathrm{III}) + \varepsilon \sin (\mathrm{I} + \mathrm{III}))$$

and

$$(x + \eta y + \varepsilon z) ,, (\cos \mathrm{II} + \eta \sin \mathrm{II}) ,, (\cos \mathrm{IV} + \varepsilon \sin \mathrm{IV}) = (x + \eta y + \varepsilon z) ,, (\cos (\mathrm{II} + \mathrm{IV}) + \varepsilon \sin (\mathrm{II} + \mathrm{IV}))$$

also that

$$x + \eta y + \varepsilon z = (x + \eta y + \varepsilon z) ,, (\cos I + \varepsilon \sin \mathrm{I}) ,, (\cos \mathrm{I} - \varepsilon \sin \mathrm{I}) = (x + \eta y + \varepsilon z) ,, (\cos \mathrm{II} + \eta \sin \mathrm{II}) ,, (\cos \mathrm{II} - \eta \sin \mathrm{II}).$$

Wessel then studies the effect of alternate horizontal and vertical rotations. Representing the radius in its first position by s and in its final position by S, and denoting the arcs in order by I, II, III, * * * *VI*, he obtains the formula

$$S = s ,, \mathrm{I}' ,, \mathrm{II}' ,, \mathrm{III}' ,, \mathrm{IV}' ,, \mathrm{V}' ,, \mathrm{VI}'.$$

In this connection he observes that such factors as V′ ,, VI′ can be transferred to the first member by using their reciprocals in inverse order, as

$$S ,, \mathrm{VI}^{-\prime} ,, \mathrm{V}^{-\prime} ,, \mathrm{IV}^{-\prime} = s ,, \mathrm{I}' ,, \mathrm{II}' ,, \mathrm{III}' ,, .$$

These results are applied to the solution of spherical polygons and the determination of the properties of spherical triangles. As in the case of plane polygons, I, II, III, etc., represent the exterior angles and sides in order, the odd numbers the angles, and the even numbers the sides. Supposing the angles and the sides of a polygon known except one angle and two sides, or two angles and a side, or three angles, or three sides, the unknown parts can be determined by the equation

$$s ,, \mathrm{I}' ,, \mathrm{II}' ,, \mathrm{III}' ,, \mathrm{IV}' ,, \mathrm{V}' ,, \mathrm{VI}' ,, \ldots ,, N' = s,$$

where s is indeterminate, and may be supposed equal to r, εr, or ηr. The effect of the rotations indicated by this equation is to submit the sphere alternately to rotations about the axis of the horizon and the axis of the vertical circle so that each point of the sphere describes first a horizontal arc which measures the first exterior angle of the polygon, then a vertical arc containing as many degrees as the first side of the polygon, then a new horizontal arc which measures the second angle, etc. The sphere finally returns to its original position, while each of its points has described as many horizontal arcs as the polygon has angles and as many vertical arcs as it has sides.

While Wessel's results, as obtained by these alternate rotations, are correct so far as they go, he fails to observe that a general rotation must be compounded of three rotations about the axes ε, η, ε or η, ε, η. Stranger still he makes no study of rotations about the real axis. Thiele, in his introduction to Wessel's memoir, shows how easy it would have been to go a few steps further and arrive at the notion of quaternions. But be that as it may, Wessel deserves great credit for having devised the only successful method of dealing with line-segments in space previous to the work of Hamilton beginning in 1843.

Unmindful of Euler's demonstration of the real value of $(\sqrt{-1})^{\sqrt{-1}}$ Argand endeavors to show that such an expression may be used to represent a directed line in

space. Français tries to solve the problem by the use of imaginary angles, but frankly acknowledges his failure. Servois sees with remarkable clearness what is needed, but is unable to reach it. He says:

The table of double argument which you (Gergonne) propose, as applied to a plane supposed to be so divided into points or *infinitesimal* squares that each square corresponds to a number which would be its *index*, would very properly indicate the length and position of the radii vectores which revolve about the point or central square corresponding to ± 0; and it is quite remarkable that if we designated the length of a radius vector by a, and the angle it makes with the real line......, -1, ± 0, $+1$...... by α, the rectangular coordinates of its *extremity remote from the origin* by x, y, the real line being the axis of x, the point would be determined by $x+y\sqrt{-1}$...... It is clear that your ingenious tabular arrangement of numerical magnitudes may be regarded as a central slice (*tranche centrale*) of a table of triple argument representing points and lines in tri-dimensional space. You will doubtless give to each term a trinomial form; but what would be the coefficient of the third term? For my part I cannot tell. Analogy would seem to indicate that the trinomial should be of the form $p\cos\alpha+q\cos\beta+r\cos\gamma$, α, β, and γ being the angles made by a right line with three rectangular axes and that we should have

$$(p\cos\alpha+q\cos\beta+r\cos\gamma)\ (p'\cos\alpha+ q'\cos\beta+r'\cos\gamma) = \cos^2\alpha+\cos^2\beta+\cos^2\gamma=1.$$

The values of p, q, r, p', q', r' satisfying this condition would be *absurd*, but would they be imaginaries, reducible to the general form $A+B\sqrt{-1}$?

As we all know now, these non-reals which Servois could not determine may be identified with the $+i$, $+j$, $+k$, $-i$, $-j$, $-k$, of Hamilton's Quaternions.

In 1799, in his first published paper, *Demonstratio nova theorematis omnem functionem algebraicam rationalem integram unius variabilis in factores reales primi vel secundi gradus resolvi posse*, the celebrated Gauss, then only twenty-two years of age, says:

By an imaginary quantity I always understand here a quantity contained in the form $a+b\sqrt{-1}$, so long as b is not zero. * * * If imaginary quantities are to be retained in analysis (which for many reasons seems better than to abolish them, provided they are established on a sufficiently solid foundation) it is necessary that they be considered as equally possible with real quantities, on which account I should prefer to include both real and imaginary quantities under the common designation *possible quantities*. * * * A vindication of these (*i. e.*, imaginary quantities), as well as a more fruitful exposition of the whole matter, I reserve for another occasion.

This occasion, however, does not seem to have come till more than thirty years later. In the *Göttingische gelehrte Anzeigen* of April 23, 1831, in an account by Gauss of his own paper *Theoria residuorum biquadraticorum, Commentatio secunda*, we read:

Our general arithmetic, so far surpassing in extent the geometry of the ancients, is entirely the creation of modern times. Starting originally from the notion of absolute integers, it has gradually enlarged its domain. To integers have been added fractions, to rational quantities the irrational, to positive the negative and to the real the imaginary. This advance, however, has always been made at first with timorous and hesitating step. The early algebraists called the negative roots of equations false roots, and these are indeed so when the problem to which they relate has been stated in such a form that the character of the quantity sought allows of no opposite. But just as in general arithmetic no one would hesitate to admit fractions, although there are so many countable things where a fraction has no meaning, so we ought not to deny to negative numbers the rights accorded to positive simply because innumerable things allow no opposite. The reality of negative numbers is sufficiently justified since in innumerable other cases they find an adequate substratum. This has long been admitted, but the imaginary quantities—formerly and occasionally now, though improperly, called impossible—as opposed to real quantities are still rather tolerated than fully naturalized, and appear more like an empty play upon symbols to which a thinkable substratum is denied unhesitatingly by those who would not depreciate the rich contribution which this play upon symbols has made to the treasure of the relations of real quantities.

The author has for many years considered this highly important part of mathematics from a different point of view, where just as objective an existence may be assigned to imaginary as to negative quantities, but hitherto he has lacked opportunity to publish these views, though careful readers may find traces of them in the memoir upon equations which appeared in 1799 and again in the prize memoir upon the transformation of surfaces. In the present paper

the outlines are given briefly; they consist of the following:

Positive and negative numbers can only find an application when the thing counted has an opposite which when conceived of as united with it has the effect of destroying it. Accurately speaking, this supposition can only be made where the things enumerated are not substances (objects thinkable in themselves), but relations between any two objects. It is postulated that these objects are arranged after a definite fashion in a series, *e. g.*, A, B, C, D, * * * and that the relation of A to B can be regarded as equal to that of B to C, etc. The notion of opposition involves nothing further than the *interchange* of the terms of the relation so that if the relation of (or transition from) A to B is considered as $+1$ the relation of B to A must be represented by -1. So far then as such a series is unlimited on both sides, every real integer represents the relation of a term arbitrarily taken as origin to a definite term of the series.

If, however, the objects are of such a kind that they cannot be arranged in one series, even though unlimited, but only in series of series, or, what amounts to the same thing, they form a manifoldness of two dimensions; if there is the same connection between the relations of one series to another, or the transitions from one to another, as in the case of the transition from one term of a series to another term of the same series, we shall evidently need for the measurement of the transition from one term of the system to another, besides the previous units $+1$ and -1, two others opposite in character $+i$ and $-i$. Obviously we must also postulate that the unit i shall always mark the transition from a given term of the one series to a definite term of the immediately adjacent series. In this way the system can be arranged in a two-fold manner in series of series.

The mathematician leaves entirely out of consideration the nature of the objects and the content of their relations. He has simply to do with the enumeration and comparison of the relations. So far as he has assigned sameness of nature to the relations designated by $+1$ and -1, considered in themselves, he is warranted in extending such sameness to all four elements $+1$, -1, $+i$, $-i$.

These relations can be made intuitive only by a representation in space and the simplest case, where there is no reason for arranging the objects in any other than quadratic fashion, is that in which an unlimited plane is divided into squares by two systems of parallel lines intersecting at right angles, and the points of intersection are selected as the symbols. Every such point has four adjacent points, and if we designate the relation A to a neighboring point by $+1$, the relation to be denoted by -1 is determined of itself, while we can select which of the two others we please for $+i$, or can take the point to be denoted by $+i$ at pleasure on the *right* or *left*. This distinction between right or left so soon as we have fixed (at pleasure) upon forwards and backwards *in* the plane, and above and below with respect to the two sides of the plane is completely determined *in itself*, although we can convey our own intuition of this difference to others *only* by reference to actually existent material things. But when we have decided upon the latter we see that it is still a matter of choice as to which of the two series intersecting at one point we shall regard as the principal series and which direction in it shall be considered as having to do with positive numbers. We see further that if we wish to take $+1$ for the relation previously expressed by $+i$, we must necessarily take $+i$ for the relation previously expressed by -1. In the language of mathematicians this means that $+i$ is *a* mean proportional between $+1$ and -1, or corresponds to the symbol $\sqrt{-1}$. We say purposely not *the* mean proportional because $-i$ has just as good a right to that designation. Here then the demonstrability of an intuitive signification of $\sqrt{-1}$ has been fully justified and nothing more is necessary to bring this quantity into the domain of objects of arithmetic.

We have thought to render the friends of mathematics a service by this brief exposition of the principal elements of a new theory of the so-called imaginary quantities. If people have considered this subject from a false point of view and thereby found a mysterious obscurity, this is largely due to an unsuitable nomenclature. If $+1$, -1, $\sqrt{-1}$ had not been called positive, negative, imaginary (or impossible) unity, but perhaps direct, inverse, lateral unity, such obscurity could hardly have been suggested. The subject which, properly enough, in the present treatise has been touched upon only incidentally the author has reserved for a more elaborate treatment in the future where also the question will be answered as to why the relations between things which present a manifoldness of more than two dimensions cannot furnish still other classes of magnitudes admissible in general arithmetic.

Such was Gauss's masterly presentation of the underlying principles of the treatment of the imaginary. In Germany the impulse given by his commanding influence is felt even to the present day.

Buée's memoir *Sur les Quantités Imaginaires*, read before the Royal Society of London in 1805 and covering 65 pages of the Philosophical Transactions of 1806, is somewhat

vague and disappointing. He describes $\sqrt{-1}$ as follows:

> $\sqrt{-1}$ is the sign of perpendicularity $\sqrt{-1}$ is not the sign of an arithmetical operation, nor of an arithmetico-geometric operation, but of an operation purely geometric. It is a purely descriptive sign which indicates the direction of a line without regard to its length.

Near the close of his paper he investigates what becomes of the conic sections when their coordinates become imaginary and decides that the circle passes into an equilateral hyperbola in the plane perpendicular to the plane of the circle and similarly for the other conics.

A further discussion of the justly celebrated epoch-making memoir of Argand and the contributions of himself, Français-Gergonne and Servois to the *Annales de Gergonne* from 1813 to 1815 is rendered the less necessary by reason of Houel's republication of all these papers in 1874 and their translation into English by Hardy in 1881.

It is interesting to note the early view of imaginaries entertained by so distinguished a mathematician as Cauchy. In his *Cours d' Analyse*, 1821, we read:

> In analysis we apply the term symbolic expression or symbol to every combination of algebraic signs which signifies nothing by itself or to which we attribute a value different from that which it naturally ought to have. * * * * Among the symbolic expressions whose consideration is of importance in analysis we ought especially to distinguish those which are called imaginary. * * * * We write the formula
>
> $$\cos(a+b)+\sqrt{-1}\sin(a+b)=$$
> $$(\cos a+\sqrt{-1}\sin a)(\cos b+\sqrt{-1}\sin b).$$
>
> The three expressions which the preceding equation contains * * * * are three symbolic expressions which cannot be interpreted according to generally established conventions and represent nothing real. * * * * The equation itself, strictly speaking, is inexact and has no meaning.

In 1849, however, in a paper *Sur les quantités géométriques*, in which he gives suitable credit to Argand, Français and others, he acknowledges:

> In my *Analyse algébrique*, published in 1821, I was content to show that the theory of imaginary expressions and equations could be rendered rigorous by considering these expressions and equations symbolic. But after new and mature reflections the better side to take seems to be to abandon entirely the use of the sign $\sqrt{-1}$ and to replace the theory of imaginary expressions by the theory of quantities which I shall call geometric.

Having defined the term geometric quantity exactly as we now define the term vector and shown when two geometric quantities are equal, he continues:

> The notion of *geometric quantity* will comprehend as a particular case the notion of *algebraic quantity*, positive or negative, and *a fortiori* the notion of *arithmetic quantity*. * * * We must further define the different functions of these quantities, especially their sums, their products and their integral powers by choosing such definitions as agree with those admitted when we are dealing with algebraic quantities alone. This condition will be fulfilled if we adopt the conventions now to be given.

Then follow the definitions called for, together with a treatment of the whole subject fully up to modern demands. Cauchy observes that a large part of the results of the investigations of Argand and others would seem to have been discovered as early as 1786 by Henri Dominique Truel, who communicated them about 1810 to Augustin Normand, of Havre.

In 1828 there appeared in Cambridge, England, a remarkable work by Rev. John Warren, entitled *A Treatise on the Geometrical Representation of the Square Roots of Negative Quantities.* Though this book has latterly received scant credit, its merits were fully recognized by De Morgan and acknowledgments of indebtedness were frankly made by Hamilton.

Throughout Warren's work the term quantity, like Cauchy's geometric quantity, indicates a line given in length and direction. Some of his definitions are as follows:

> The sum of two quantities is the diagonal of the parallelogram whose sides are the two quantities. The first of four quantities is said to have to the

second the same ratio which the third has to the fourth; when the first has *in length* to the second the same ratio which the third has *in length* to the fourth, according to Euclid's definition; and also the angle at which the fourth is inclined to the third is equal to the angle at which the second is inclined to the first, and is measured in the same direction. Unity is a positive quantity arbitrarily assumed from a comparison with which the values of other quanties are determined. If there be three quantities such that unity is to the first as the second to the third, the third is called the *product*, which arises from the *multiplication* of the second by the first. If there be three quantities such that the first is to unity as the second is to the third, the first quantity is called the *quotient*, which arises from the *division* of the second by the third.

The fundamental laws of algebra as governing these quantities are established in their utmost generality with a rigor of reasoning that has probably not been surpassed. The author even goes so far as to deduce the binomial formula, to develop many series and to apply the methods of the differential and integral calculus to quantities of the class defined. In form Warren's work is intensely algebraic and fairly bristles with formulæ.

To sum up:

Caspar Wessel, in 1797, published the first clear, accurate and scientific treatment of directed lines in the same plane, as represented by quantities of the form $a+b\sqrt{-1}$, establishing the laws governing their addition, subtraction, multiplication and division, and showing these quantities to be of practical value in the demonstration of theorems and solution of problems; he also worked out a partial theory of rotations in space, so far as they can be decomposed into rotations about two axes at right angles.

Not very much later, 1799, Gauss indicated that he was in possession of a method of dealing with quantities of the form $a+b\sqrt{-1}$ which would consider them as equally possible with real quantities, but its fuller exposition was deferred till 1831.

Buée's paper of 1805 lays great emphasis upon $\sqrt{-1}$ as the sign of perpendicularity, but fails to give any satisfactory interpretation of the product of directed lines.

Argand's famous memoir of 1806 is hardly in danger of receiving too much credit. Though written after Wessel's paper there is not the slightest probability that Argand had any knowledge of the Norwegian surveyor, and, in fact, certain of his theorems are established less rigorously than by Wessel. Argand gave numerous applications of his theory to trigonometry, geometry and algebra, some of which are very noteworthy, especially his demonstrations of Ptolemy's theorem regarding the inscribed quadrilateral and of the fundamental proposition of the theory of equations.

The contributions of Français, Gergonne and Servois, 1813–1815, served to do away with some of the errors into which Argand had fallen and thus to give a clearer insight into the fundamental notions of the subject.

Though Warren's book of 1828 contains definitions differing but little from those of Wessel and Français and a notation which seems only a modification of that of Français, his generalized treatment of directed lines in the plane must be regarded as highly original.

Cauchy's work lay in the extension and development of the labors of his predecessors rather than in the introduction of new ideas.

Such were the beginnings of the study of the geometric representation of the imaginary which has led in modern times to the establishment of such great bodies of doctrine as the theory of functions on the one side and quaternions on the other, with the Ausdehnungslehre occupying a position between. Who can tell what the next century will bring forth?

W. W. BEMAN.

UNIVERSITY OF MICHIGAN.

*EIMER'S EVOLUTION OF BUTTERFLIES.**

THE criticism, by Professor Minot, of the second part of Eimer's work, *'Artbildung und Verwandtschaft bei den Schmetterlingen,'* which appeared in SCIENCE at the beginning of last year (January 3, 1896, Vol. III., No. 53), gives me occasion to again explain Eimer's evolutionary theory, which, so far as I can see from Minot's article, has in many respects been misunderstood. It seems as though Minot were not well acquainted with Eimer's earlier works on the markings of animals, works in which questions of evolution were already discussed. And, as Eimer's present views on this subject are chiefly founded on the results of these earlier works, it is easy to understand why many assertions which need these results for their proof, seem incomprehensible to Minot. Minot calls Eimer 'an enthusiastic opponent of Darwin's theory of natural selection.' It is true that through his investigations on the markings of different groups of animals Eimer became more and more confirmed in his opinion that natural selection was of no moment for the origin of species. This view is expressed in the 'Butterflies,' with the distinct reservation (see p. 68) that he acknowledges the efficiency of natural selection in preserving and intensifying such characters as have previously been developed by other agencies to such an extent as to become useful to the organism in question. Eimer, then, occupies the same position that Mivart defended against Darwin (see 'Origin of Species', Germ. ed., 1876, p. 249 ff.) and he is a decided opponent of the teleological views spread by some of Darwin's followers rather than by the latter himself.

According to Eimer species originate by organic growth, a term first defined by him in his 'Origin of Species.' In the constitutional changes which organisms undergo during life in consequence of external influences, such as climate, food, etc., he sees the first agents that cause the development of new characters. These changes first reveal themselves as growth-phenomena. It is the struggle for existence that gives rise to selection from among these changes, that rejects or adopts. I must consider it a misrepresentation to call this view of the origin of species a bold hypothesis. It is merely the result of investigations which prove plainly that, in the more sensitive representatives of a species, external influences can and do produce individual variations, and that we find these as aberrations in contiguous districts and as species in those that are more distant. Eimer first mentions this thesis in his work on *'Das Variiren der Mauereidechse'** and makes it probable by his observations; more striking proofs, however, are given in his work on the 'Evolution of Butterflies.' Our native horadimorph butterflies, such as *Vanessa levana* and *V. prorsa*, *Pieris bryoniae* and *napi*, make it sufficiently obvious that external influences are no indifferent factors in the formation of organisms. A variation of temperature to which the chrysalis is exposed produces, from the eggs of one and the same species, butterflies which differ so much in their external structure that for a long time they were held to be separate species. Dorfmeister† and Weismann‡

showed by experiment—they let the chrysalids of the *prorsa* generation develop at low temperature, those of the *levana* at high temperature—that both butterflies belong to one and the same species. Similar experiments have of late been made by Merrifield* and Standfuss† and have revealed still more astonishing phenomena in a great number of butterflies. They all tend to prove that the forms developed in heat or in cold respectively, always possess those qualities which characterize variations and nearly allied species of these butterflies living exclusively in warmer or colder climates. And not only the markings, but also the form of the wings and the whole configuration of the animal change. In his criticism Minot does not so much as mention these facts, which Eimer regards as a proof that the views on which his theory is based are correct; on the contrary, he particularly emphasizes that Eimer's theories are founded only on the study of the markings of animals and the geographical distribution of forms. It is true that, guided by the results of his earlier researches, Eimer regards these markings as the most characteristic signs of affinity between the various species.‡ And he considers as a further proof of the correctness of this assumption the results of the artificial development of butterflies in lower or higher temperatures in their relation to the geographical connection of forms.

‡Darwin also came to the same conclusion, as he says: "We shall hereafter see, especially in the chapter on Pigeons, that coloured marks are strongly inherited and that they often aid us in discovering the primitive forms of our domestic races." Animals and Plants under Domestication, Vol. I., p. 29. London, 1868.

Eimer's theory further materially differs from that of Natural Selection in its explanation of liabilities and tendencies to changes.

Natural selection presupposes the most varied liabilities to changes, in order to become efficient in the production of forms; Eimer, on the contrary, is of opinion that individuals can only follow prior determined, *i. e.*, definite tendencies of evolution (not predetermined tendencies, as Minot wrongly understands). This 'Orthogenesis,' in opposition to Nägeli's view, does not always tend towards perfection, but often towards simplification and retrogression. In its rudiments this law shows itself in the markings of animals, inasmuch as the primitive form of longitudinal stripes becomes spots, transverse stripes, and uniformity of color. This rule, which Minot wishes to be 'proved, not proclaimed *ex cathedra*,' is followed, as is shown by Eimer's researches, by the ontogenesis and phylogenesis of reptiles,* birds,† and mammalia. Simroth‡ found this law confirmed in Limaces, I myself in the markings on the shells of marine gastropods.§ Although the physiological cause and, therefore, the necessity of this curious phenomenon has not yet been ascertained, yet, as it repeats itself in so many different groups of animals, it cannot be denied the importance of a fact. and Würtenberger's* works and my own investigations of the shells of Molluscs have shown that other morphological characteristics apart from the markings produce regular changes in a definite direction. Taking this into consideration I do not consider it a 'bold hypothesis' on Eimer's part, when he believes he has found a confirmation of his law of markings in the case of butterflies, for "any hypothesis which explains various large and independent classes of facts rises to the rank of a well-grounded theory." (See Darwin, Animals and Plants under Domestic. Vol. I., p. 8, 1868.) In the systematic part of his two volumes on 'Butterflies' Eimer shows how seemingly insignificant variations of the markings from the original form invariably develop into definite characteristics of new aberrations and species, the changes being dependent upon physiological conditions. It can therefore not be asserted that butterflies are subject to the most multifarious liabilities to change. The markings of *Segelfalter* and of Swallow-tails can be reduced to one common scheme, which, as the illustrations show, is most simply represented by the markings of *Papilio Podalirius*. This scheme of markings consists of eleven bands which extend over the wings in a fixed direction parallel to the axes of the body. They are called longitudinal bands and are always connected with certain veins of the wings. These eleven bands can undergo several variations. They can become broader and vanish altogether by means of lateral combination, become shorter in the direction from the abdomen or head, and sometimes quite disappear, or develop into single spots and form a transverse marking by means of dark colored scales which show themselves on the transverse veins of the wings. In this way the *Segelfalter*, as well as the Swallow-tails, develop new forms, which, from showing only slight aberrations from the original form in the beginning of the evolutional series, differ materially from it in the end. The same law which thus determines the evolution of the members of a group also determines that of the groups themselves. Each succeeding one begins its development at a somewhat higher stage than its predecessor. Variations which are an exception in the lower groups become the rule in the higher ones. This is the reason why the representatives of the first groups of the *Segelfalter* "have markings very similar to the original form, while the third group contains butterflies which closely resemble the Swallow-tails."

The primitive Swallow-tails have attained a much higher degree of development than the primitive *Segelfalter*, but still it is not difficult to recognize that, although they are not immediately allied to the *Segelfalter*, yet their development follows the same direction. The Swallow-tails still possess indications of a separation of bands, which in the *Segelfalter* have coalesced. Furthermore, fragments of markings which still occur in forms closely related to the Swallow-tails show that the development of their markings depends on the same conditions as those of the *Segelfalter*. It would lead me too far to describe in detail the directions of evolution which manifest themselves in the various groups. I will only mention that the tendency of the bands to broaden and to coalesce can be traced throughout the entire groups of *Segelfalter* and has produced almost melanotic forms in the group of *Asterias* of the Swallow-tails. Further, the shortening of the bands from abdomen to head is characteristic of both *Segelfalter* and Swallow-tails. In both groups the

Contrb. to Knowledge, 1889. The same: Phylogeny of an Acquired Characteristic. Proceedings of the Amer. Philosoph. Soc., Vol. XXXII., No. 143, 1895.

*Würtenberger: Studien über die Stammesgeschichte der Ammoniten, Leipzig, 1880.

bands become spots and combine into a transverse marking by the agency of dark colored scales on the transverse veins. If we neglect secondary differences of markings in the two groups of *Papilio*, we have to assume that they originated in complete independence of each other—a direct relationship cannot be proved—according to the same definite laws of development.

In entire groups as well as in single species, no matter whether they live in the same or in different districts, the law of a definite direction of evolution is shown in homogenesis, or independent similarity of evolution. As examples, Eimer cites the North American *Turnus* and the south European *Alexanor* (which is also found in Asia Minor), of *Segelfalter* the South American *Agesilaus*, *Protesilaus* and the European *Podalirius*.

The phenomenon of homogenesis is of importance as a proof that it is not geographical distribution in the sense of local separation on which the development of different directions of evolution depends.

This short exposition of the direction of evolution in the genus *Papilio* seems to me to show that it was not arbitrariness on Eimer's part to select *Papilio Podalirius* as the ancestral form of his group of butterflies. He has shown, by his study of the markings of one series of forms, that those of all its members can be reduced to one and the same scheme, and that aberrations from the forms which are nearest to this original scheme of markings vary so as to form transitions to nearly allied species, which again are connected with more distant species, and the conclusions drawn from the study of these phenomena are confirmed by the results of geographical distribution. This being so, I cannot understand how Minot can doubt that Eimer's assertions are correct.

Neither does Minot agree with the explanation of the sudden appearance of a second perfectly dark-colored form of the feminine *Papilio Turnus* by 'development by jumps' (*Halmatogenesis*). This singular form of feminine *Turnus* called *var. Glaucus*, which occurs exceptionally in the North and regularly as a summer generation in the South of the United States, seems not to be connected by any transitions with the normal feminine animal. Minot, however, believes it possible that in former times transitional forms existed. It seems to me a matter of course that a highly developed form like *Papilio Turnus var. Glaucus* has to undergo several variations of markings during the chrysalis stage before it can leave it in its present form. But in comparison with the difference between the variation of another species and its original form, that between *Turnus* and *var. Glaucus* remains just as striking, whether we know that during the chrysalis stage forms of transition temporarily occur or that in former times forms existed which made the transition from the normal feminine *Turnus* to the *var. Glaucus* somewhat more gradual. As it at present appears, *var. Glaucus* is a form produced by *Halmatogenesis*. Eimer's theory necessarily leads to the conviction that qualities produced by external influences are transmitted to the descendants of those who have acquired them, an assumption for which Minot demands proofs. The experiments of Weismann on *Polyommatus phlœas*, which are mentioned in the *Zoologische Jahrbücher*, 1895, *Abteilung für Systematik*, show that this transmission of qualities from their possessor to his descendants really occurs.

It is by no means every individual that undergoes a change through the influence of unaccustomed external influences. Several preserve the parental aspect. And as the parental characteristics were not from the beginning such as they are at present, but are, as is shown by experiment, the result of certain conditions, the transmission

to the descendant of these parental characteristics which have also been acquired is the clearest proof of the heredity of acquired characteristics.

In spite of all his objections to the theoretical part of Eimer's work, Minot allows that the 'Butterflies' are "valuable from the standpoint of the systematic entomologist, since his groups are natural ones and his grouping of the species is in the main correct."

In his grouping of the butterfly species Eimer was guided by those laws which his study of the markings of other groups of animals had caused him to regard as the general rule, and which he therefore considers himself entitled to apply hypothetically to butterflies. The grouping of species being admitted by Minot to be natural, this is sufficient proof of the correctness of those theories which this grouping presupposes. In designating those groups as natural ones in which longitudinally striped forms develop into spotted, transversely striped and unicolored ones, Minot acknowledges the law of evolution of markings in its full significance.

Darwin, himself, in his 'Origin of Species,' employs similar proofs to show that the same groups of pigeons are descendants of *Columba livia*. Their phylogenetic connection is to him proved by the fact of elements of the markings of *Columba livia* appearing in the plumage of our tame pigeons.

The ontogenetic development of those groups of animals the markings of which Eimer has studied is to him a valuable argument for the correctness of the law laid down for their phylogenesis. Similar investigations made by E. Haase on the evolution of the markings on the wings of the chrysalis of *Papilio Podalirius*, in so far as his limited materials permitted decisive conclusions, completely confirm Eimer's assertions.

These and other researches on the same subject led me to make similar investigations, the results of which I am about to publish. They furnish the best proofs for the laws found by Eimer. My specimens showed that not only single characteristics develop in the way described by Eimer, but that the markings of *Papilio Podalirius* or *Machaon*, as a whole, undergo an evolution in which the degrees of *Alebion*, *Glycerion* or the *Turnus* group are clearly distinguishable.

It would be of great interest to investigate the American forms of *Papilio* in order to see whether Eimer's 'bold hypotheses,' as Minot calls them, apply here. On the basis of arguments which have hitherto been considered customary and convincing in biology, I believe I have shown that Eimer far from rejecting Darwin's theory as a whole, because 'it does not explain the origin of variations.' He knows as well as Minot that Darwin does not even attempt an explanation of their origin. As, however, the theory of the origin of species demands an explanation of the origin of new characters, Darwin has not, as Eimer shows, explained that which he wished to explain. Eimer, on the contrary, shows in the 'Butterflies' how new qualities develop; he explains the causes of their formation and traces the laws of their development. This necessarily led to his well founded theory of the origin of species by means of variations and their propagation. The arguments contained in the 'Butterflies' must convince anybody who examines them somewhat more closely than Minot, that, as Eimer shows, variations and, therefore, the origin of species do not take place arbitrarily in the most varied, but according to Orthogenesis in a few absolutely definite, directions, not influenced by any sort of natural selection and without any reference to teleology. Eimer's theory of orthogenesis, proved as it is by facts, certainly negatives the function of

natural selection as a transforming factor, but acknowledges its preserving and intensifying power. This is the only concession that can be made to the theory of natural selection as long as the results of Eimer's investigations have not been refuted by facts, not, as heretofore, by words. Till then, I believe, one cannot deny to Eimer's work the appreciation contained in Minot's introductory sentences: "If Professor Eimer's claims are correct, his researches mark one of the great epochs of biological discovery."

I wish to state that this is merely a preliminary exposition of Eimer's views, intended for rectifying the erroneous judgment expressed by Minot. Eimer's work on organic evolution (Macmillan, 1889) gives a detailed account of his theoretical views and of the facts on which they are based. His work on Butterflies, which was criticised by Minot, serves to furnish further corroboration of the theory advanced in the above work on evolution. In his lecture at Leyden he has also given a complete exposition of his ideas in their relation to the theory of selection and of Weismannism; against the latter Eimer takes a most decided stand (see 'Extract from Comte Rendu des Séances du 3me Congrès international de Zoologie, Leyde, 16–21 Sept., 1895). This lecture includes the programme of Eimer's most recent exposition of 'Orthogenesis' embodied in a work that is just about to appear.

Countess Dr. M. von Linden.
Zoological Institute, Halle.

The Countess von Linden's article presents the arguments in favor of Eimer's theory. A reply seems unnecessary and others will judge of the value of the theory. Eimer's earlier papers I knew; whether I understood them or not I cannot decide. All of Eimer's evidence is essentially that he *asserts* that of a group of living species a certain form or certain forms are ancestral types. If one denies that assertion Eimer cannot *prove* that it is correct, but unless he *proves* it his deductions remain hypotheses. The reader is asked to consider whether Countess von Linden offers proof that a certain species in any given case is the ancestral race.

For the sake of a fair discussion I am glad that the preceding communication from Professor Eimer's assistant appears in Science.

Charles S. Minot.

*PROGRESS OF PROFESSOR KITASATO'S INSTITUTE FOR INFECTIOUS DISEASES AT TOKIO.**

Among the changes in the general condition of Japan, due to the introduction of Western civilization, one of the most noteworthy is the entire revolution in the system of medicine; the old Chino-Japanese school has been superseded by the scientific system of the West, and the striking feature of the new medicine in this empire is the ascendency of the bacteriological element. The center of this movement is seated at the 'Institute for Infectious Diseases,' directed by Dr. Kitasato.

To Mr. Fukusawa belongs the credit of having initiated the introduction of this branch of medical science into this country by building, at his own expense, a laboratory for Dr. Kitasato, upon the latter's return from Germany in 1892. I do not mean to ignore what has been done at the University and elsewhere; I only emphasize the great impetus that the study of the micro-organisms has enjoyed since the establishment of the above mentioned laboratory. Subsequently the Institute became connected with the 'Sanitary Society of Japan.' The ensuing year the Imperial Diet

* This article was prepared at the request of the Editors. Dr. Nakagawa is a graduate of Princeton University.

granted the sum of 20,000 yens ($10,000) for the building and equipment of the Institute, and also yearly the subsidy of 15,000 yens, which was to be continued for three years. At the expiration of the term the same subsidy has been renewed for the same number of years. Thus the Institute has no relation with the Imperial University of Tokio and is directly under the patronage of the Minister of the Interior.

The work of the Institute is divided between the scientific and clinical departments; the scientific department is subdivided into the laboratory for original researches and the didactic branch for the postgraduate course in practical bacteriology.

(a) *Laboratories for Original Researches.*

It is here that Dr. Kitasato continues his investigations, and I take this opportunity to recapitulate some of the more important reports issued from his laboratory.

(1) *Tsutsugamushi.*—This malady, which is endemic in certain parts of this country, presenting the clinical feature resembling that of the typho-malarial fever, has been ascertained to be the pathological condition due to the parasitic invasion of the red blood corpuscles analogous to that which obtains in malaria. Moreover, the plasmodia of tsutsugamushi is described as being morphologically very nearly related to that found in malaria, but differing from the latter parasites in this important respect: viz., that the tsutsugamushi parasites are refractory to all the staining procedure now in use.

(2) *Bacillus Pestis.*—The discovery of the plague bacilli is too well known to need mentioning in this connection were it not for the fact that it seems to be utterly unknown to the world that the bacilli claimed to be the specific germ of the plague by Dr. Yersin is absolutely different from that described by Dr. Kitasato. Dr. Kitasato's bacilli are almost exactly like those of chicken cholera (in shape), *i. e.*, each bacillus presents the appearance of a pair of diplococci, and is, as a rule, considerably smaller than Dr. Yersin's bacillus. Kitasato's bacilli can be stained according to Gram's methode, while the other is decolorized by the regular procedure. Kitasato's bacillus is surrounded by a distinct capsule which is wanting with Yersin's. Moreover, Kitasato's bacilli are motile, but Yersin's bacilli are not. There are thus at present two distinct bacilli held to be the ætiological factor of the disease in question. It is to be hoped that the members of the commission sent out to Bombay will help to clear up the confusion.

(3) *Anti-diphtheritic serum.*—The preparation of the serum has been carried on in this Institute previous and up to the opening of the Imperial Government Serum Institute, in June, 1896. I might mention in this connection that Dr. Kitasato is the chief advisor of the Serum Institute.

(4) *Anti-cholera serum.*—I have had occasion elsewhere to make a brief report of Kitasato's work on this subject (*Brit. Med. Jour.*, July, 1896). I shall only mention here that the result was in so far encouraging that it justifies making further trials of this remedy in the future epidemics. Neither shall I enter into detail concerning the experimental part of the work in which Dr. Kitasato seeks to prove the anti-toxic property of the cholera-serum; suffice it to say that the conclusion he has reached is at variance with that of the Berlin school.

(5) *Lepra.*—Dr. Kitasato has been engaged in the most thoroughgoing investigation into the treatment of leprosy. It is reported that he is in possession of the remedy which goes under the name of 'Leprine,' though I am unable to say that its preparation is, in any way, analogous to that of tuberculine, as its name seems to suggest. It is expected that Dr. Kitasato will favor the world by publishing his full report in the near future.

(6) Investigations concerning the typhoid and erysipelas serums, as well as various other researches in all the fields of micro-biology, are being pursued by the Professor himself, as also by the assistants under his supervision. There are 6 assistants and nearly 10 'extra-ordentliche' assistants.

The studio for micro-photography has recently been built and is equipped with Zeiss's complete apparatus.

The library, though in its infancy, contains most of the works on infectious diseases, bacteriology and hygiene, and is supplied with the medical periodicals in the English, French, German, Italian and Japanese languages. I take this opportunity of acknowledging the receipt of the following official publications from America: U. S. Department of Agriculture, Bureau of Animal Industry; Bulletins U. S. Treasury Department, Marine Hospital Service, Health Reports, etc.; City of Brooklyn, Department of Health, Annual Report. We should be glad to receive more of the American publications.

(b) *Practical Course in Bacteriology.*

The utility of the knowledge of micro-organisms being admitted, it was deemed desirable to give a practical course of bacteriology for the benefits of the licentiates in medicine. The first course was given in March, 1894. The course is of three months' duration and is conducted by Professor Kitasato, who gives a series of lectures on the pathogenic bacteria. The assistants take their turn and serve as demonstrators. The laboratory for instruction accommodates 50 students and is provided with all necessary appliances. Over 200 physicians have gone through the course. It is with great pleasure that we mention in this connection that the American naval surgeon and an English naval surgeon have availed themselves of the facilities of the Institute and have pursued their investigations for a considerable length of time.

(II.) THE CLINICAL DEPARTMENT.

The wards in all are capable of holding 50 patients. The admission is limited to cases of contagious diseases (except cholera and smallpox). Diphtheria, tuberculosis, typhoid, tetanus and relapsing fever are the principal maladies on the list. I may mention in this connection that 180 cases of leprosy have been treated in the out-patient department with the injection of 'Leprine,' and 4 cases of complete recovery, beside several cases of improvement, have been reported. The diphtheria statistics show a mortality of 9,44%.

A. NAKAGAWA.

INSTITUTE FOR INFECTIOUS DISEASES, TOKIO.

NINTH ANNUAL MEETING OF THE ASSOCIATION OF ECONOMIC ENTOMOLOGISTS, DETROIT, MICH., AUG. 12–13, 1897.

THE Association met in room 212, Central High School building, immediately following the adjournment of Section F. Thirteen active members were present, together with many visitors, prominent among the latter being Dr. C. A. Dohrn, Professor E. B. Poulton and Dr. C. S. Minot. The attendance for the four sessions averaged about 35. The address of the retiring President, Professor F. M. Webster, Wooster, Ohio, treated of 'The Present and the Future of Applied Economic Entomology in the United States,' and contained, among other very interesting features, an admirable tribute to the value of the systematist and a somewhat caustic criticism of the 'species maker,' helpful suggestions for the experiment station worker, and a very frank discussion of the unfortunate results which attend the attempts sometimes made to combine politics and science.

The following were elected to active membership: G. B. King, Lawrence, Mass.; Gerald McCarthy, Raleigh, N. C.; E. P. Felt, Albany, N. Y.; A. F. Burgess, Mal-

den, Mass.; W. B. Barrows, Agricultural College, Michigan; R. H. Pettit, Agricultural College, Michigan; W. S. Blatchley, Indianapolis, Ind.

The following were elected foreign members; Claude Fuller, Richard Helm, both of Perth, West Australia. These additions increase the members of this Association to 93 active and 31 foreign members.

The following papers were read and discussed: 'Additional Observations on the Parasites of *Orgyia leucostigma*;' 'Temperature Effects as Affecting Received Ideas on the Hibernation of Injurious Insects;' 'A Valuable Coccid;' 'Notes on the Common House Fly,' L. O. Howard; 'Notes on Certain Species of Coleoptera that attack Useful Plants' (abstract), F. H. Chittenden; 'An Experience with Paris Green,' T. D. A. Cockerell; 'Insects of the Year,' E. A. Onerod;' 'A Fungus Disease of the San Jose Scale,' P. H. Rolfs; 'The San Jose Scale in Michigan;' 'A Malodorous Carabid, *Nomius pygmaeus*,' W. B. Barrows; 'A Study of Lepidopterous Insects at Light and at Sugar;' 'Vernacular Names of Insects,' C. P. Gillette; 'A Study of the Possible Origin and Distribution of the Chinch Bug,' F. M. Webster; 'Notes on Cape of Good Hope Insects,' C. P. Lounsbury; 'The Giant Cactus and Its Fauna,' H. G. Hubbard; 'Insects of the Year in Ohio,' F. M. Webster–C. W. Mally; 'On the Preparation and Use of Arsenate of Lead,' A. H. Kirkland. A number of papers, the authors of which were not present, were read by title and will be included, probably, in the published proceedings of the Association. Among these papers were the following: 'Notes on Insecticides,' 'The Peach Twig Borer, *Anasia lineatella*,' C. L. Marlatt; *Ledra perdita* vs. *Centruchus liebeckii*,' F. W. Goding; 'Notes sur les Insectes Nuisibles observés en Algerie et en Tunisie pendant l'année 1896–97,' 'Notes sur les Insectes Nuisibles observés en France,' Paul Marchal; 'Notes on Injurious Insects of Norway and Sweden,' W. M. Schoyen.

Several resolutions were passed, among which were (1) a resolution requesting the publication of the proceedings as a bulletin of the Division of Entomology, U. S. Dept. of Agriculture and (2) expressing familiarity with the efforts of the State of Massachusetts to exterminate the gypsy moth and commending the results already accomplished.

The election of officers resulted as follows: President, Herbert Osborn, Ames, Iowa; First Vice-President, Lawrence Bruner, Lincoln, Neb.; Second Vice-President, C. P. Gillette, Ft. Collins, Colo.; Secretary–Treasurer, C. L. Marlatt, Washington, D. C.

The next meeting of the Association will be held at Boston, Mass., August 19–20, 1898.

A. H Kirkland,
Secretary pro tem.

CURRENT NOTES ON ANTHROPOLOGY.

THE ANCIENT SLAVONIC TYPE.

There prevails considerable uncertainty as to the appearance of the ancient Slavs. Professor Lubor Niederle, of Prague, however, in a recent work, and also in *Globus*, No. 24, advances what seems sufficient reasons to pronounce them to have been blonde and dolichocephalic. He quotes the earliest authentic references in classical authorities, all of which refer to the fair complexion and reddish blonde (ξανθός) hue of the Slavic peoples. In these respects the descriptions are the same as of the early Goths.

It is true that at present, and also in many interments of ancient dates, brachycephalic skulls are found in considerable numbers; and persons with dark complexions and dark hair are numerous in Slavic countries. Professor Niederle explains this change of type by two agencies, intermixture with other stocks, and by civilization.

About the latter he writes: "We cannot demonstrate the connection, but there is a striking parallelism between advancing civilization and the gradual increase of the skull in width." This is an interesting statement, and it is to be hoped that Professor Niederle will make it the subject of a special study in the future.

THE LANGUAGE OF THE MAMS.

THE Mams lived in the northwestern part of Guatemala and enjoyed an advanced indigenous civilization. Their capital was Zakeleu, the White Land, meaning the place of culture; for in all the Maya dialects white is a metaphorical expression for civilized conditions. By some the Mams have been held to be the earliest of the Mayas to become sedentary and city builders. Their ancient native name was Zaklohpakap, the White Cultivators.

A vocabulary of their tongue was printed by Father Reynoso, at Mexico, in 1644, but is now so scarce that it is inaccessible to students. The Comte de Charencey has, therefore, conferred a favor on Americanists by republishing it in the *Actes de la Société Philologique*, Tome XXV. It contains nearly three thousand words, and offers ample material for comparisons with the other dialects of the stock. It is closely akin to the Quiche, and is still spoken in a number of villages. The volume may be had from C. Klincksieck, 11 Rue de Lille, Paris.

D. G. BRINTON.

UNIVERSITY OF PENNSYLVANIA.

NOTES ON INORGANIC CHEMISTRY.

IN 1887 Professor Chroustchoff announced the discovery of a new element in the monazite sand of North Carolina, to which he gave the name 'russium.' This discovery has not been confirmed by any other chemist, but, induced by the supposed discovery of 'lucium,' Professor Chroustchoff has again gone over his work, publishing a short report in the *Journal* of the Russian Chemical Society. According to *Nature* he has from 25 kilos of rare earths extracted 35 grams of russium. It has an atomic weight of 70.5 and its spectrum is characterized by a group of green and violet lines. He also claims to have resolved cerium into five components, differing in physical properties, and having atomic weights respectively of 138, 140, 142, 146 and 156.5. He also finds, in addition to Auer's neodymium and praseodymium, a third new constituent of didymium to which he gives the name glaukodymium. A detailed account of his work is promised at an early date.

IN the last *Berichte*, W. Hentschel gives an account of further investigations on the chloride of nitrogen, in which he finds the compound normally formed to have the formula NCl_3, confirming the work of Gattermann and of Balard. He also finds that this compound can take up more chlorin until its composition seems to be NCl_5, but this is really a solution of chlorin in the chloride of nitrogen. His method of forming this exceedingly explosive and dangerous compound is to bring together solutions of ammonium chlorid and sodium hypochlorite, and dissolve the chlorid of nitrogen formed, which partly separates out and partly remains in solution, in benzine.

IN the *Pharm. J. Trans.*, C. H. J. Warden describes the method used in the Calcutta Medical Depôt for the production of a pure silver nitrate from coin silver. The silver used contains copper and is dissolved in nitric acid and a portion of the silver nitrate crystallized out in the usual way. As soon as the mother liquor is so concentrated that the silver nitrate crystallizing out is contaminated with copper it is evaporated to dryness, finely powdered and placed in a glass funnel stopped by an asbestos plug. It is then washed with pure concentrated

nitric acid until perfectly white. The copper nitrate is very easily soluble in the nitric acid, while the silver nitrate is almost wholly insoluble. Any trace of silver dissolved by the nitric acid can be recovered by treating with salt. This is by far the simplest method proposed for obtaining pure silver salts from coin or plate, and deserves trial in our laboratories.

H. TRYLLER describes in the *Berichte* a new turbine for laboratory use, which lays claim to the advantages of steadiness, noiselessness and economy of water. To the axle is attached a circular piece of wire gauze, rotating in a thin cylindrical space. The jet of water strikes the edge of the gauze at a tangent and escapes by a pipe in the center opposite the end of the axle. A speed of four thousand revolutions is easily attained. The turbine is to be manufactured by M. Koehler and Martini, of Berlin.

J. L. H.

SCIENTIFIC NOTES AND NEWS.

THE meeting of the British Association at Toronto has proceeded in accordance with the program. The members in attendance, about 1,200 in all, have been received with great hospitality, and many important papers have been given before the sections. The meeting is still in progress as we go to press, and we shall defer an account of the proceedings until next week.

THE British Medical Association will meet in Edinburgh in 1898, under the presidency of Professor T. Grainger Stewart.

ACCORDING to the latest lists about 5,000 members had expressed their intention of attending the 12th International Medical Congress meeting this month in Moscow; about half of the number are Russians, 800 are from Germany, 600 from Austria, 500 from France, 250 from England and from Italy, and 100 from America.

THE sixty-ninth meeting of German Men of Science and Physicians will, as we have already noted, be held at Brunswick from the 20th to the 25th of September. The social arrangements begin on the preceding day with a reception, a banquet and an exhibition of sports. The first general meeting opens on the 20th with the reports of officers, followed by two addresses, one by Professor Richard Meyer, of Brunswick, on the relations between chemical research and technical chemistry; the other by Professor Waldeyer, of Berlin, on fertilization and inheritance. At the second general session Professor Orth, of Göttingen, will speak on medical instruction and the practice of medicine, and Dr. Hermann Meyer, of Leipzig, on central Brazil. Several joint meetings of the sections have been arranged, one of special interest being a discussion of scientific photography in its applications to the natural sciences and to medicine.

THE Scientific Society of Argentina, says *Nature*, is organizing a Congreso Cientifico Latino Americano, to be held at Buenos Ayres in April next, in commemoration of the twenty-fifth anniversary of its foundation. The Congress will be under the patronage of the President of the Argentine Republic and the Ministers of Justice, Foreign Affairs, and Public Instruction. There will be seven sections, dealing respectively with exact sciences (pure and applied mathematics, astronomy, geodesy and topography), engineering, physics and chemistry, natural science, medical sciences (including hygiene and climatology), anthropology and sociology.

WE noticed sometime since the appointment of a committee to investigate the condition of the Coast and Geodetic Survey. This committee has now presented a report which will not be made public. The Washington *Star*, however, states that it is practically decided that a successor to the present Director of the Survey will be appointed, and that the selection will be made without reference to political considerations and on the grounds of scientific standing.

PROFESSOR C. B. HOWES, writing Dr. Thurston to inform him of the condition of the work of the Huxley Memorial Committee, states that the statue is now in progress, in the hands of Mr. Ford, the sculptor, and promises to be most excellent. It is to be a seated figure in a gown,

to be placed at the bottom of the steps in the Hall of the Natural History Museum leading up to the statue of Darwin. It is in white marble. The design for a medal for the Royal College of Science is thought admirable, and the medal is in preparation. It is further possible, if subscriptions continue, that a medal may be instituted, open to the world of biologists, and awarded by the Royal Society. The Messrs. Macmillan, as a memorial, also, are publishing a fine edition of Huxley's scientific papers; the first volume being now well in hand. There are on the list many subscriptions from America and it is not too late for others to be sent.

THE monument to Darwin to which we have several times referred was unveiled on August 10th. It is in his native town of Shrewsbury and in front of the school which for nine years he attended. The monument, the work of Mr. Horace Montford, represents Darwin seated in a chair holding some manuscripts from which his face is turned as if deep in thought, while at the foot are a number of volumes representing his finished works.

DR. VICTOR MEYER, professor of chemistry at the University of Heidelberg, died at Heidelberg of apoplexy on August 8th, aged 49 years. Meyer filled chairs of chemistry at Stüttgart, Zurich and Göttingen and finally succeeded Bunsen at Heidelberg in 1889. His work was in organic chemistry, more especially relating to the nitro-compounds and the vapor density of volatile compounds.

WE regret also to record the deaths of M. Quantin, assistant in the taxidermic laboratory of the Paris Museum of Natural History, and of Dr. W. Petzold, a writer on geography and astronomy.

WE learn from *Cosmos* that the new buildings of the Paris Museum of Natural History have not been completed as soon as was expected, the work of construction having been stopped for three months owing to the delay in voting funds for its completion. Work has, however, now been resumed and it is hoped that the galleries will be open to the public by the beginning of next year. The lower floor contains the collections of comparative anatomy which are being arranged under the direction of MM. Filhol and Jarvis. The collections of anthropology and paleontology are being put in order on the upper floor. The collections have hitherto been badly arranged in crowded quarters, but will now be exhibited to great advantage. New catalogues giving full details are also being prepared.

AN exhibition has been opened in the zoological galleries of the Paris Museum of Natural History containing the collections in natural history made by M. Chaffanjon on his expedition to Siberia and Central Asia.

AN exhibition of navigation instruments was opened in London on August 5th, intended especially to illustrate the progress that has been made in the art of navigation during the Queen's reign. There are in all about two hundred exhibits including a sextant by Bird, said to have been used by Captain Cook, lent by the Royal Astronomical Society, Lord Kelvin's deflector for adjusting the compass, his sounding machine and other instruments of historical or scientific interest.

WE learn from *Die Natur* that the committee for the introduction of the produce of German colonies held its general meeting in Hamburg, recently. The committee has founded a journal called *Der Tropenpflanzer*, and has established in Berlin a permanent exhibition of colonial imports. The committee offers prizes for the development in the African colonies of new resources, such as the making of wine, the cultivation of coca and quinine, the production of gum arabic, etc.

THE Hungarian government has completed the necessary arrangements for the construction, without delay, of a subway beneath the Danube at Budapest on the same principle as that of the new Blackwall tunnel under the Thames in London.

A TELEGRAM from San Francisco states that Commissioner-General Herman, of the United States Land office, has arrived there for the purpose of conferring with Professor Hilgard and other members of the State Forestry Commission upon the subject of the forest reserves, of which about 6,000,000 acres are located in California.

There has been established in Switzerland a weather bureau. A dispatch is sent each evening from Zurich giving the weather probabilities for the next twenty-four hours. The predictions are based on data received from the principal meteorological stations of Europe combined with experience of local conditions. The dispatch is further distributed by telephone to those communes prepared to subscribe 10 frs. per month for the service.

The Royal 'Institut für Pflanzen Physiologie and Pflanzen Schutz,' in Berlin, offers to give, without charge, information and advice regarding diseases and injuries of cultivated plants. It is also prepared to send agents to examine the plants without charge beyond the railway ticket which, in certain cases, will also be paid by the Institute.

An International Conference of Legal Medicine convened at Brussels on August 2d. It was welcomed by the Belgian Minister of Justice, and Dr. Veleminckx, the Honorary President of Committee of Organization, gave an account of preceding conferences. A number of topics were discussed concerning the relations of medicine and law—among them the treatment of insane criminals, regarding which a series of recommendations was passed by the Congress.

The Eighth Annual Congress of French-speaking Neurologists met at Toulouse on August 2d. Addresses were made by Dr. Ritti and Dr. Labéda, on Esquirol, who was born at Toulouse, and Pinel, who was born near by, as the inauguration of memorials to be erected in their memory. Pinel and Esquirol, as is well known, were leaders in the reforms in the treatment of the insane. Before their time it was usual to treat the insane as intermediate between criminals and wild animals. They first showed that insanity is a disease, and in many cases a curable disease.

We noted last week the loss, in the shipwreck of the *City of Mexico*, of the collections and apparatus of the zoological expedition sent by Columbia University to Alaska. Word has just been received by mail that the party lost all the results of their season's work. They left Sitka in the *City of Mexico*, of the Alaska S. S. Co., on August 4th, taking the outside passage. At 4:20 a. m. on the 5th, in a heavy fog, the vessel attempted to enter Queen Charlotte Sound, through Dixon's Channel, and ran upon a reef known as Devil's Rock, sinking in two hours. The crew and passengers were transferred to life boats and after seventeen hours of exposure reached the Indian village at 11 p. m., where they were hospitably cared for until the arrival of the *City of Topeka*, three days later. The Columbia party lost all their collections, drawings, notes and apparatus, excepting three microscopes. They will reëstablish the old station at Port Townsend, Puget Sound, for the remainder of the season.

M. Robert Wurtz, professor at the Paris School of Medicine, one of the leading French bacteriologists, has been chosen for a mission in Abyssinia. He will go to Adis Abeba, where, after having organized a department of vaccination, he will study the rinderpest and similar infectious maladies.

The steamer *Belgica*, with the Gerlache Antarctic expedition on board, sailed from Brussels on August 16th. The Belgian Chamber of Representatives has made an additional appropriation of 60,000 frs. for the expedition.

A message has been received from Turnavick, on the coast of Labrador, dated July 28th, stating that the steamer Hope, with Lieutenant R. E. Peary's expedition abroad, had touched there that day and sailed again on its way to Greenland. All on board were well.

A serious epidemic of small-pox is feared at Montreal. The city has been divided into twenty-four districts, and there will be a house-to-house vaccination.

Dr. Marten, chief of Dr. Roux's laboratory of the Pasteur Institute, has been awarded an honorary gold medal by the French government for his work in epidemiology.

Señor Canovas, by his will, has left to the National Library, at Madrid, a collection of 30,000 books, many of which are very rare.

A building for a free library and historical society, to cost $20,000, has been given by Mr. Spalding, of Chicago, to Athens, Pa., his native town.

An explosion occurred recently in a laboratory at Saint Michael-de-Maurienne, where carbide of calcium was being manufactured. The building was destroyed and one workman was killed and three others were seriously injured.

The unpublished journals of the great naturalist Audubon, written in French, are being translated for publication in English by his granddaughter, Miss Maria Audubon.

Ginn & Co. announce that they will publish at once 'Stories of Insect Life,' by Professor Clarence M. Weed, of the New Hampshire College of Agriculture and Mechanical Arts. The book is designed to give information to the child regarding the lives of the insects, and to stimulate pupils to fuller observation of insects out-of-doors.

The trustees of the Boston Public Library have authorized the publication, in their bulletins, of an exhaustive 'Bibliography on the Anthropology and Ethnology of Europe,' prepared by Professor William Z. Ripley, of the Massachussetts Institute of Technology, lecturer in anthropo-geography at Columbia University. This list of references will include about 1,500 titles, taken in every instance from the original sources. It embodies the raw materials of the papers on the Racial Geography of Europe now appearing in successive numbers of the *Popular Science Monthly*, afterward to be published in book form. Every precaution has been taken to insure completeness and accuracy; most of the living authorities will have corrected and supplemented the lists of their own works in proof. The bibliographical systems of Minot and Wilson will be employed, with a complete subject index. A special feature will be the reference to original maps, whether linguistic, somatological or ethnographical. It is worthy of note that practically all of the titles in this recent field of investigation are upon the shelves of the Boston Library, proof positive of the possibilities for research from original sources which are now afforded by our great American collections.

We are glad to welcome a new edition of the 'Dynamic Sociology,' of Professor Lester F. Ward, published by the Appletons. The first edition, issued in 1883, was very fully reviewed in four articles included in the second volume of this Journal, and no material changes have been made in the present edition. There is much to be said for not attempting to recast a work that represents a given epoch in the history of a new science. The further development of the author's views on psychology have been given expression in a separate volume (the 'Psychic Factors of Civilization,' 1893), and this is a better plan than re-writing a standard book. An interesting preface to this edition of the 'Dynamic Sociology' notes that fourteen years ago, when the work was first published, the word *sociology* was used but rarely; there were but few books on the science, no journals, and no university chairs. Now all is changed; the word is on the lips of everyone, and the science, if given as wide a range as Professor Ward's book, bids fair, as he says, to become the leading science of the twentieth century. The preface gives some account of the suppression of the Russian translation of the book, which was widely commented on in the daily papers several years ago. The suggestion is made that the title suggested socialism and dynamite to the Council of Ministers, a very dangerous combination from their point of view. A Polish translation appears also to have been suppressed, but four Russian translations of the 'Psychic Factors of Civilization' have been made.

Professor Bailey's 'Principles of Fruit Growing' (The Macmillan Co) is both practical and scientific. As all that the author writes —and it is not little—the book is worth reading, both by the practical gardener and by the student. After an introduction covering the kinds of fruits, the geography of fruit growing and its methods, chapters are devoted to location and climate, the tillage of fruit lands, their fertilization, their planting and their care, followed by chapters on disease and insects, and on harvesting and marketing. Professor Bailey makes many acute remarks, as when he calls spraying 'insurance' and gives as one of its uses 'waking up the horticulturist.' This volume is the fifth in this 'Rural Science Series,' edited by the author of this volume, which has fulfilled the promise of the publishers to be 'readable, simple, clear-cut, practical, up-to-date, and thoroughly scientific and reliable.'

WE have received from W. B. Saunders, Philadelphia, a bulky volume by Drs. George M. Gould and Walter L. Pyle, entitled "Anomalies and Curiosities of Medicine: Being an encyclopedic collection of rare and extraordinary cases, and of the most striking instances of abnormality in all branches of medicine and surgery, derived from an exhaustive research of medical literature from its origin to the present day, abstracted, classified, annotated and indexed." We should scarcely suppose that the compilation of this volume would repay the labors of the compilers and the costs of publication. A miscellany like this can scarcely be regarded as a contribution, such as Geoffroy Saint-Hilaire made, toward an explanation of the formation of monstrosities in its relation to zoological theory. Still the study of variations is of the utmost importance for zoology, and extreme cases of human abnormality may prove useful to the student of the theory of evolution. The cases given in the work are treated critically, full references being given and a fairly conservative attitude being adopted. But one modern instance is worth more than many old saws, and it is rather a contribution to folk-lore than to medicine to relate stories, qualified as incredible, such as that of Countess Margaret and her 365 infants.

THE fifty-eighth anniversary meeting of the Fellows of the Royal Botanic Society was held on August 10th, in the Society's gardens at Regent's Park, Mr. C. Brinsley Marlay presiding. According to the report in the London *Times* six new Fellows were elected and eleven candidates were nominated for election at the next meeting after the vacation. The annual report of the Council to the Fellows stated, among other things, that tentative arrangements had recently been made for taking visitors round the gardens by members of the staff to point out objects of special interest. Free tickets had been granted during the year to about 800 students. About 50,000 specimens of plants had been given for educational purposes. The Council had decided to open a school of practical gardening and to hold examinations and grant certificates for gardeners. The new school had already been officially recognized by the Technical Education Board, which was sending pupils to attend its classes and had voted an annual grant of £100 to the Botanic Society in aid of the scheme. The number of Fellows on the books had risen from 1,700 in 1887 to 2,000 in 1897. The report having been presented, a discussion followed in which Sir Blundell Maple, M. P., proposed that the Society should build in the gardens a club-house to which the Fellows could have access. He volunteered to lend the Society a sum of £3,000 for this purpose, the money to be repaid by easy instalments. He anticipated that such a club would be a large source of income to the Society, and he added that if it should eventually prove to be a loss the loss should be his. Eventually the report was adopted unanimously. The chairman announced that the promise of a new lease of the gardens, to commence on the termination of the present one, had been definitely given by her Majesty's Commissioners of Woods and Forests for a fresh term of 31 years, and that the Society's outlook was now most promising.

THE research scholars of the British Medical Association (the scholarships being of the value of $750 each) have handed in their reports. Dr. J. B. Leathes has been engaged in a research into the nature of mucin-like proteids contained in ovarian cysts. Dr. J. S. R. Russell has been studying the tracts of the medulla oblongata and the cervical nerves. Dr. Swale Vincent has been studying the physiology of the suprarenal capsules.

ACCORDING to the *British Medical Journal* the new State Institute for researches with Röntgen rays, or 'actinography' (as the new term runs) has been opened under the direction of Professor Grunmach. It is close to the Charité Hospital and its clinical institutions, and has every convenience for the transport of severe cases. Needless to say, the Institute is furnished with all the newest appliances; it contains a laboratory, a lecture theatre, photographic rooms, and a room where the patients are examined according to the usual methods before being subjected to the X-rays. In the first week after the opening of the new Institute,

two of the rare cases of inversion of the viscera were sent from the Charité, actinography revealing the inverted displacement of the organs, their size and motions, with the greatest distinctness.

PROFESSOR GOTCH, Waynflete professor of physiology at Oxford, in his annual report states that the following research work has been in progress during the present year: (1) The Professor and Mr. G. J. Burch. Upon the Electromotive properties of Malapterurus electricus, being a continuation of previous work on the subject. (2) The Professor. On the Tendon Effect and on the Influence of Temperature upon Excitability and Conductivity. (3) The Regius Professor of Medicine. On Muscular Contraction. (4) Dr. J. S. Haldane and Professor Lorrain Smith. On the Oxygen Tension of Arterial Blood, the Detection of Carbonic Oxide in Air and Blood, the Action of Nitrites upon Blood, etc. (5) Dr. Mann. On the Changes in Nerve Cells Associated with their Activity. (6) Mr. W. H. Vernon. On the Respiratory changes of Cold-blooded Animals. (7) Miss Huie. On the Changes in the Cells of Drosera. (8) Professor Sherrington and Mr. J. S. Macdonald. On the Neuro-muscular Mechanism of Respiration. (9) Mr. Buddicom. On the Effect of Ether and other Gases upon Nerve Excitability, etc. (10) Mr. W. E. Stainer. On the peptic properties of Pitcher-plant liquid.

UNIVERSITY AND EDUCATIONAL NEWS.

THE University of Berlin has set an example in maintaining academic freedom by electing as Rector for the coming year Professor Gustav Schmoller, who is supposed to have incurred the enmity of the Emperor by the character of his lectures on political economy.

THE Paris correspondent of the London *Times* states that under the law of July 10, 1896, decrees have been issued for the government of universities. Each university is to have a council consisting of the rector, the heads of faculties, and two delegates of each faculty elected triennially by the professors. The council, subject in certain cases to the approval of the supreme education council, will have control over the teaching, discipline, and property of the university. It will, however, have merely a consultative voice on the finances, and on the creation, abolition or transformation of professorships, for the State will continue to pay the stipends. The maintenance of buildings, on the other hand, will fall on the university, and must be defrayed from students' fees or from endowments. The State takes the fees for examinations and State diplomas, but all other fees go to the university treasury. It will, therefore, be to the interest of each university to attract as many students as possible. The receipts of Paris University are estimated at 600,000f. and of Lyons at 130,000f., but Besançon and Clermont have at present only 700f. or 800f., and will obviously have to solicit subsidies either from the State or from local bodies. Failing this, the smaller universities are likely to succumb. One of the features of the new system is that a student will, as in Germany, be able to migrate from one university to another without lengthening his studies or delaying his degree.

THE Swiss government has for several years offered *courses de vacance* or university extension courses at Lausanne and Geneva, which have been attended by numbers of American, English and other foreign students. The Department of Public Instruction has now decided to supplement the courses given by the Faculty of Letters by adding to the program scientific and historical excursions, with lectures given gratuitously by university professors.

AT the meeting of the London County Council on July 20th the Technical Educational Board presented their report for the preceding quarter. It stated that arrangements had been made with King's College and University College for evening courses of instruction, to be given to persons who are engaged during the day, in civil engineering, mechanical engineering, architecture, natural philosophy, pure mathematics, electrical engineering, magnetic and electric currents, the strength of materials, the principles of practical physiology, experimental physics, and the teaching of mathematics. Arrangements had also been made for a Saturday morning course to teachers to be held at Bedford College. In the 'teachers' courses the aim would be to explain the best educational methods of teaching the respective

subjects to their pupils and not to prepare the teachers to pass examinations. The payments made by the Board during the quarter amounted to about $100,000.

DEGREES of a 'Chicago National University' have been for sale in London. The *Times* states that it has "received a telegram from Mr. Francis Harkins, the Chancellor of the Chicago National University, stating that that university repudiates agents who offer degrees on payment of a guinea." There are five hundred colleges and universities in the United States entitled to confer degrees, but the 'Chicago National University' is not one of them.

MISS MARTHA VEEDER has been appointed professor of mathematics at Huguenot College, Cape Colony.

M. JUMELLE has been made assistant professor of botany, and M. Beaulard assistant professor of physics in the faculty of sciences of Grenoble, and M. Brunhes has been made professor of physics in the faculty of sciences of Dijon.

DISCUSSION AND CORRESPONDENCE.

METEOROLOGICAL OBSERVATIONS DURING AN ATLANTIC VOYAGE.

TO THE EDITOR OF SCIENCE: A few notes of meteorological interest, made during a recent voyage from New York to Rio de Janeiro, may not be unwelcome to the readers of SCIENCE. The trip itself is one which cannot fail to interest anyone who has a knowledge of meteorology, for the steamer route crosses several of the great wind and calm belts of the world, and the characteristic features of each belt are brought into striking contrast as the ship passes from prevailing westerlies into 'horse latitudes,' and then successively through N. E. trades, 'doldrums' and S. E. trades, the voyage ending in the 'horse latitude' belt of the southern hemisphere. A teacher of meteorology who has the good fortune to take this voyage must constantly feel how grand an opportunity the trip would give him to teach the great facts of this science to a class of students, if he could only take his class with him. It would indeed be field-work, if such an expression may be used, on a magnificent scale.

The formation of cumulus clouds over islands has been noted by many observers in different parts of the world, but is always of interest. On June 8th, early in the afternoon, the ship was some distance to the eastward of Bermuda. The sky, except in the west, was covered with strato-cumulus clouds, and the wind was light from S. S. W. On the western horizon the sky was lighter, and the sun was shining on the low clouds. In this direction, which was that in which Bermuda lay, could be seen a considerable number of cumulus clouds, radiating from below the western horizon, and moving across the sky to the N. E. These were evidently coming from the island, for in no other part of the sky were there any other cumulus clouds to be seen. The cumuli diminished rapidly in size as they increased their distance from their place of origin, and they were lost sight of as the ship's course took her farther away from the island. Another observation of cumulus clouds formed over land was made on the morning of June 23d, when about 10 miles off shore north of Bahia. There was a splendid development of cumuli over the land, the shore-line to the north and south being outlined in the sky by the clouds, while over the ocean there were only a few scattered trade cumuli.

On June 9th (noon position 29°43′ N., 59°23′ W.), between 3 and 4 p. m., there was a fine opportunity to study the growth and mechanism of an advancing thunderstorm. These storms, as the writer has pointed out in an account of the thunderstorms of New England, advance, when well developed, in a long line (storm-front), but their activity is not the same all along this line. In some places where there is more active convectional ascent the rain and thunder and lightning are more severe, while at other points along the same storm-front there may be no rainfall, and the clouds may even seem to break away. It is these apparent breaks along the storm-front which give rise to the common statement that thunderstorms 'divide' over an observer, when in reality there is no true division. On the day in question the thunderstorm when first noted was a single large cumulo-nimbus cloud to the west, and the heaviest rain could distinctly be

seen falling below those portions of the cloud which showed the most lofty tops. These extra heavy rains were seen falling in three places under the main mass of the cloud, and over each of these places the height of the cloud was noted as being especially great. While watching this cumulo-nimbus it was noticed that to the south of it there were some cumulus clouds developing rapidly into cumulo-nimbus and becoming part of the same cloud as that first observed. In this way the storm-front was seen to be extending itself gradually farther and farther to the south, new cumulus clouds continually developing into cumulo-nimbus and joining themselves to the parent storm-cloud. Thus, in an hour, more or less, a long storm-front was developed, extending with a N. E.-S.W. front across the greater part of the western sky. The movement was to the N. E. Careful observation of the storm-front showed distinctly the centers of extra heavy rainfall and the lighter portions in between these centers. In these lighter portions either no rain or light rain was falling.

At sunset on June 18th, in the S. E. trade (noon position, 0°16′N., 38°47′W.), some observations of degrading cumuli were interesting. The afternoon sky was fairly well covered with trade cumuli, some of the clouds almost reaching the cumulo-nimbus stage. Just after sunset careful observation of these clouds showed them dissolving and toppling over in a very striking manner. The clouds were in shadow, and were clearly outlined against the bright sunset sky behind them. The process of disintegration was of two kinds. In the first the top of the cloud, bending forward in the direction of the prevailing wind, simply toppled over to the northwest, breaking off, so to speak, at the point where it joined the main cloud mass. The upper part, after toppling over, quickly evaporated, and a long line of trade cumulus would thus lose their typical form and become flattened out into a long band, which, in time, also broke up and faded away. In the second kind of disintegration the *shape* of the top of the cloud remained unchanged during the process, the cloud particles simply dissolving as they kept their position with relation to the cloud base. Thus, in a few minutes, only the skeleton of the top of the cloud was left, and this also soon evaporated, leaving, as in the first process, a long flat band of cloud. The two processes were quite distinct, although they were both processes of disintegration. In explanation of these phenomena, it appeared that the second kind of disintegration occurred only when the clouds were large and well developed, *i. e.*, where the supply of water vapor from below was probably still active, and the effect of the faster-moving upper air in blowing forward the top was not so strong in consequence. For this reason, the cloud kept its shape well, dissolving without being toppled over, while in the first case the cloud was probably in a stagnant condition, and its top offered less resistance to being blown over.

In conclusion, a few directions of cloud movement may be of interest, although comment on them is omitted by reason of lack of time at the present writing.

June 10. Lat. 26°58′N., Long. 55°41′W. Cirro-stratus from N. W. June 11. Lat. 23° 45′N., Long. 52°30′W. Cirrus from S. W. June 13. Lat, 16°35′N., Long. 47°34′W. Low fracto-cumulus from E. N. E. R. DE C. WARD.

BUENOS AYRES, July 14, 1897.

SCIENTIFIC LITERATURE.

Travels in West Africa. By MARY H. KINGSLEY. The Macmillan Co. 1897. 16 plates, 29 illustrations in the text. Pp. xvi. + 743. Cloth $6.50

An interesting book in spite of some defects. It takes Miss Kingsley 120 pages to get settled down to the subject of her 'beloved southwest coast;' and the 400th page is passed before you reach the valuable portion of the book.

There is little, past, present, or even future, in connection with West Africa that does not get a touch from her facile pen. There is however an easy flippancy of manner in the story

which carries you on, in spite of a knowledge that the writer is 'on very thin ice' a great deal of the time. The off-hand way in which some rather serious problems are treated is hardly fair, even if we should agree with the sarcasm of some of her criticisms of isolated cases. For example, much space is devoted to the discussion of the subject of the need of proper training for the natives. And where the mission schools go to work along the lines of tailoring, printing, bookbinding, etc., many of which West Africa is certainly not in the most urgent need of, we should agree that they could employ their time much better upon such subjects as smithwork, carpentering or, best of all, agriculture. Our young lady, however, is never tired of quoting Dr. Nassau, for his great learning on the subject of the blacks, and then pokes fun at his efforts and those of some of his colleagues, forgetting that the seamy side of the garment of civilization as applied to the West Coast is probably just as apparent to them as to her, during her rather picnic-like excursions into these regions.

As an example, "even sewing, washing and ironing are a little ahead of time. When the girl goes back to her husband with her two dresses she will soon be reduced to a single dirty rag, which will answer for dress, sheet, towel and dish cloth, and then think of the envy and jealousy of the other wives, and the state of feeling induced by such style. Washing and ironing become parlor accomplishments when your husband does not wear a shirt, and when household linen is non-existent." One might ask the question, What is the use of trying to do anything?

Some of the writer's conclusions form very interesting reading. One of the new reasons given for polygamy is that the man of the house is liable to 'get enough to eat.' But when, after getting fast on a sand bank, and trying to haul off by fastening a line to the trees on the main bank, and succeeding in pulling away the bank, trees and all, she reaches the conclusion that 'Africa is a rotten Continent,' we cannot help but admire the stoical cheerfulness which is certainly the prime requisite for a good traveller.

One of her 'hints to travellers' is worthy of a wide circulation, namely, to always learn the word or words meaning 'I don't know!' as instances are given where four villages and two rivers have been graced with words bearing this interpretation, which does not tend to geographical clearness. Another feature might be added, drawn from the fact that rivers are sometimes called by one name going up, and by another going down the current.

The really valuable portion of the book is that devoted to the subject of fetichism. Here the inspiration of Dr. Nassau is plainly visible, though there is a great deal of clear insight and common sense used in the interpretation of some of these difficult problems. It is a valuable contribution to our knowledge of the subject.

There are five appendices to the work. The first two are by the authoress upon Trade and Labor on the West Coast and upon Labor. These are followed by a chapter by Dr. Günther describing her collection of fish and reptiles. Appendix IV. is by Mr. Kirby, of the British Museum, on the insects obtained from the Ogowe region. The last is a legend of the origin of the cloth loom.

William Libbey.

Princeton University.

The Microscope and Microscopical Methods. By Simon Henry Gage. Sixth edition. Rewritten, greatly enlarged. Comstock Publishing Company, Ithaca, New York. 1896. Octavo; pp. xii+237; 165 figures, 1 plate.

The appearance of a new edition of Professor Gage's work on 'The Microscope' calls for notice, since the addition of a large number of figures and about 90 pages of new material have made it practically a new book. As stated in the preface, the plan of the work is: 'Actual experiments carried on by the student himself;' and in this respect the book is probably unique in its field, and, it is needless to say, thoroughly in accord with the modern scientific method. In the preparation of the book Professor Gage has drawn upon his long experience and numerous publications on microscopic technique, and in particular subjects has taken pains to consult specialists whose authority would not be questioned and to whom due acknowledg-

ment is made in various places. The extensive scope of the book is well shown by an outline of the various chapters: (1) The microscope and its parts. (2) The manipulation of the same. (3) The interpretation of images. (4) Magnification and measurement. (5) Drawing. (6) Micro-spectroscope and polariscope. (7) Technique of the object. (8) Photo-micrography.

To these are added a copious appendix on methods of testing and on preparing figures for publication, while the whole is terminated by an extensive bibliographical list and by a good index. The bibliography is to be especially commended for its accuracy and completeness. A careful review of its five pages of closely printed type discloses only one omission, though that is rather a striking one, the Zeitschrift für angewandte Mikroskopie.

The book is full of valuable information, not only for the student, but for those of considerable experience in microscopic technique, and the number of good hints which are given is very large. Of course, every man has his own ideas with reference to details of technique, and undoubtedly no one would agree with the exact plan outlined by the author. For instance, some would undoubtedly criticise the statements that balsam mounts should be sealed, as also that collodion is the most generally available imbedding material. Many will find fault with the detail of instruction given for the use of the mathematical tables. These are, however, particulars in which the manual is suited to the course given by Professor Gage, and easily capable of omission by those who use the book with other ideas in mind.

It may be fairly questioned whether the amount of space given to the microscope and its accessories from an optical standpoint is not excessive; as compared with Behrens, Kossel & Schiefferdecker, for instance, the extent of space devoted to this branch of the topic is rather striking. In the latter work about 30 per cent. of the space is devoted to the instrument, while 50 per cent. is spent in the consideration of the preparation of the object. In Professor Gage's book the microscope and its accessories occupy about 80 per cent. of the entire work; and even when one considers that some parts are discussed here more fully in the light of recent development in certain branches of the subject, it is still questionable whether the technique of the object has not been slighted in favor of the technique of the instrument. As the reviewer has pointed out elsewhere, it is undoubtedly by the development in the manipulation of the object that recent years have advanced so far, and it is to this advance that we are indebted for our rapidly growing knowledge with reference to more fundamental phenomena of biological science. Some years ago in his address, 'A Plea for Physiological Histology,' Professor Gage himself emphasized this side of the question. The various methods of reconstruction are, in the opinion of the reviewer, of much greater general importance to the student in every branch of biological science than some of the difficult mathematical discussions of optics which are treated at length in the book, and yet the topic of reconstruction has not even been mentioned. This is all the more striking when one recalls that we are indebted to Mrs. Gage for a most admirable and inexpensive method of reconstruction, and when the various methods have been so largely applied both by her and by the author in their various researches.

The treatment of the microscope as an optical instrument, with its various accessories, is exceedingly complete; so much so that Professor Gage gives us fourteen full pages of cuts of microscopes, in which good, bad and indifferent stands are mixed with rare impartiality. There is no discussion of the principles on which the construction of the various types is based, and no choice expressed with reference to which are the most reliable or would best perform certain sorts of work. The beginner, or even a student of some experience, would sit dazed before this collection of figures in his efforts to decide which he needed. The inclusion of so many cuts was, perhaps, a necessity of the case, seeing that the electrotypes were donated by the manufacturers and it would have been unwise to have slighted any particular firm; and yet it might have helped a little to have discussed briefly the general principles of construction involved.

Among minor defects one might mention a lack of care in type-reading, which shows itself

in the use of both m.m. and mm. several times on the same page, and in the recurrence of various misspelled names. It is certainly amusing to learn that an article can easily be made by a *tin smith.* One notices, also, an occasional slip of the pen, as a result of which figure and text do not always agree. Thus, the mechanical stage, shown in figure 69, does not possess verniers, despite the statement in the description of the cut, and the absence of this feature is undoubtedly a serious defect in the construction of the stage as compared with that of another maker which is shown in the adjacent figure. The excessive number and length of the foot-notes in the book mar the beauty of the page, and many of them might easily have been incorporated in the text. It is further true that the constant use of vulgar fractions, which have no place in a scientific text-book, is another point to be justly criticised. Their employment also is not limited to such as are difficult to translate into decimal figures, but $\frac{1}{10}$, $\frac{5}{100}$ mm., etc., are of constant occurrence.

While it would be manifestly unfair to give an idea of the book based merely on these criticisms of minor details, it is evidently impossible to do more than hint at some of the many advantageous features which it contains. The synopses of the steps in the preparation of paraffin and collodion sections are of exceeding value to any student and will doubtless save much time and many errors. Throughout the book one finds very complete cross references and satisfactory bibliographical notes which will be of constant use to the worker. Every topic is completely and concisely discussed; the order is clear and logical, and one is at a loss to suggest points that have been overlooked.

The chapter on Photo-micrography deserves especial mention. It includes much that cannot be found elsewhere and is altogether the best concise statement of the subject which is accessible. This chapter is worth more than the price of the entire work. Like the rest of the book, it is copiously illustrated; the figures are exceptionally well chosen, and among them are a couple of splendid photo-micrographs from the work of Mrs. Gage, who also drew all the original figures by which the work is illustrated. As a whole, the work is a useful and valuable addition to the manuals accessible to the American teacher and is destined to be widely and generally used.

HENRY BALDWIN WARD.

The Chances of Death and other Studies in Evolution. KARL PEARSON. Edward Arnold, London and New York. Vol. I., pp. ix+388; vol. II., pp. 460. $8.00.

Professor Pearson's essays and lectures fall into three groups. One of these is concerned with the theory of deviations from the mean in its application to vital and social phenomena, another with a criticism of certain popular writers who have exploited science for the benefit of religion and politics, and the third with studies in folk-lore and folk-customs, viewed from the light they cast on the evolution of society. All of the essays are of great contemporary interest, and have to a considerable degree the unity claimed by the author, 'the endeavor to see all phenomena, physical and social, as a connected growth, and describe them as such in the briefest formula possible.'

The essays on variation in this volume, and the series of papers on the mathematical theory of evolution published in the *Transactions and Proceedings* of the Royal Society since 1894, represent a scientific advance of great importance. Modern science pursues two main methods; it is either quantitative or genetic. The exact sciences have found in measurement a method of description so efficient, economical and universal that it must be regarded as the goal of those sciences in which description is only qualitative. The genetic method has, however, since the publication of the 'Origin of Species by Means of Natural Selection,' demonstrated its validity. Could we add to the genetic method of natural science the quantitative method of exact science a great advance would be assured.

It is not possible to describe in a few words what has in fact been accomplished since Quetelet applied the Gauss theory of the distribution of errors to vital phenomena. If any trait, such as the height of men, depends on a great number of small causes, some tending to make them smaller and an equal number tending to

make them larger, then theoretically the deviations from the mean will be distributed in a certain symmetrical fashion, and measurements show that such a distribution does in fact approximately obtain. According to the Darwinian theory such chance variations as proved useful have by natural selection been preserved, and have given rise to new species and to organic evolution. The quantitative study of these variations, especially in their relations to heredity, is, I believe, the most pressing problem of biological science. The small amount of work hitherto accomplished has been chiefly carried out in England by Mr. Galton, Mr. Weldon, Mr. Bateson and Mr. Pearson. Mr. Galton has assumed the validity of the theoretical distribution. Mr. Pearson has shown that the distribution may be complex and nonsymmetrical, and has subjected it to mathematical analyses.

Turning now to the essays in this book, which are of special value because the scientific papers of the author are of such a technical character, as to make them unintelligible to many naturalists, we find the first to be on 'The Chances of Death.' Mr. Pearson explains the theory of deviations from the mean, and shows how mortality statistics may be analyzed into five 'skew' curves. Thus 'old age' mortality includes about one-half of all deaths. The maximum of the curve is at about 71 years, but it has a 'skewness' toward youth of 0.345. The mean is at about 65 years, with a 'standard deviation' of about 13.5 years and a limit on the old age side of 106.5 years. Components are then found representing the mortality of middle age, of youth, of childhood and of infancy. In the last case Mr. Pearson found that to secure a frequency curve it was necessary to take account of antenatal mortality, and that the curve discovered corresponds fairly well with the facts.

It is quite evident that the regular frequency curve does not represent mortality statistics or, indeed, most social and vital statistics. I have in several publications claimed that the ordinary frequency curve can in all actual cases be but an approximation. Mr. Pearson's skew curves allow us to express the facts with greater approximation, just as the orbits of planets are more nearly ellipses than circles. But, in fact, the orbits of the planets are endlessly complex, and so are the distributions of errors or deviations. Mr. Pearson claims to give a simple curve for infancy, but the material is not homogeneous. Antenatal mortality is due to causes different from those of infant mortality. The mortality of infants of the two sexes, of different races, of different classes, of those born at different seasons of the year, of those legitimate and those illegitimate, of those nursed by the mother and those brought up by hand, etc., has each a different distribution. In antenatal mortality there is a maximum at each four weeks, a greater maximum in the second and third months, etc. The curve for infancy would, in my opinion, need to be further broken up, quite beyond the possibility of mathematical analysis, in order to express the facts.

The second essay analyzes certain alleged results of Monte Carlo Roulette, and shows that they are deficient in short runs to an almost impossible degree. Presumably the published figures do not represent the actual falls of the ball, or it would be easy to 'break the bank.' The author does not give this explanation, and apparently does not notice that in one case the zeros (where the money goes to the bank) are only 499 instead of a most probable 840, a return perhaps intended to encourage the gambler. I must admit that I do not think that Mr. Pearson has made the best possible use of his time in tossing shillings 25,000 times, etc., in order to test the laws of probability. He might as well measure the sides of 25,000 right-angled triangles in order to see whether the square of the hypotheneuse is really equal to the sum of the squares of the other two sides.

The third essay, entitled 'Reproductive Selection,' is concerned with a statistical study of the size of families. The material is of much theoretical interest and of the greatest practical importance. If there is a complete correlation between fertility of parent and offspring, we might expect those having large families to supplant quickly all others, whereas it is not commonly supposed that those most fertile are those most fit for society. From 4,390 families, mostly of middle and upper Anglo-Saxon stock, Mr. Pearson finds that the most frequent

family, the 'mode,' is between two and three; the median family is about $3\frac{1}{4}$ and the mean family one larger. The median fertility is, however, about $5\frac{1}{2}$, and it follows from this that the most fertile quarter of the parents produce one half of the next generation. The same general relations hold for the extensive statistics of Copenhagen families collected by Rubin and Westergaard, but the fertility is greater. In both cases there is a deficiency, according to the theoretical distribution, of families of five and six children, due probably, as Mr. Pearson holds, to voluntary control. I cannot, however, agree with him that the curve shows that control is not exercised in the case of families of other sizes, or that in the case of no children it is excessive. In the latter case there are special anatomical and physiological causes producing sterility, which would not be factors in the amount of fertility.

Mr. Pearson finds that there is a selective death-rate increasing with increased fertility, but it would only slightly check 'reproductive selection,' and he concludes that in the case of civilized man natural selection at present appears to be quite secondary to reproductive selection as a factor of progressive evolution. An extreme Neo-Darwinian might, indeed, find it difficult to tell us why families do not increase indefinitely in size, or why infant mortality does not eliminate itself. We must believe that deviations from the mean are not always stable hereditarily and are in definite directions. The degree to which individual fertility is a stable variation can only be determined by statistics not yet collected. It is, however, clear that race or class fertility, whether due to physiological or psychological causes, will in a comparatively short time produce great changes in every race and in the survival of races. Thus the Bretons are supplanting other French stocks, and our New England stock is in danger of extermination.

The essay on 'Variation in Man and Woman' occupies one-third of the first volume. As the result of some 155 cases of variation for both sexes, covering a wide field, Mr. Pearson finds that woman is, relatively to size, not less, but probably slightly more, variable than man. This is contrary to the common opinion, but had been proved previously by Mr. Galton for sensation-areas. The variation in brain-weight is of special interest, but the data are so conflicting that they are not of great value; the coefficient of variation is, however, sensibly the same for the two sexes. Mr. Pearson criticises somewhat bitterly those who have assumed, on insufficient evidence, the greater variability of the male and drawn therefrom sociological conclusions. I think, however, that the experience of those who have taught both men and women will favor the greater intellectual variability of the male. The collation of examination papers marked without reference to these matters would be of interest. Supposing the male to be more variable in intellect and character, as seems sufficiently evident from the history of civilization, it would still remain undecided whether this were due to 'nature' or 'nurture,' and sociological inferences can only be drawn with caution.

This volume contains three essays criticising, respectively, Mr. Kidd's 'Social Evolution,' Lord Salisbury's 'President's Address' before the British Association and Mr. Balfour's 'Foundations of Belief.' Mr. Pearson has rather an easy task. Mr. Kidd's book received abundant attention and was lauded by Mr. Wallace in *Nature*, but it is already half forgotten. Mr. Pearson's arguments for the comparative unimportance of intra-group selection for human progress are, however, deserving of considers ation. Most men of science will agree with Mr. Pearson's arraignment of Lord Salisbury and Mr. Balfour. It is a particularly futile form of argument to pass from *ignoramus* to *ignorabimimus* and thence to *credendum est.* Mr. Pearson holds that the comparative orthodoxy of the Conservative leaders was of much advantage to them in the last elections. The writing of books on science and philosophy is, however, a kind of demagogy of which we should be glad to see some trace in America. Mr. Pearson is undoubtedly correct in stating that thoughtful men of science do not hold the materialistic views attributed to them by Mr. Balfour, but I am not sure that his own idealism helps greatly in treating the problems of physical science. When it is said that in science we are concerned not with phenomena,

but with 'a rational analysis of the contents of the human mind,' this is a statement that does not essentially affect the methods of science; but it seems somewhat dangerous to attempt to lessen the difficulties in the way of correlating atoms and the ether with other physical phenomena by regarding them as 'conceptual limits.'

The only essay in the first volume not yet noticed is concerned with the place of women in society, and with the relations of individualism and socialism—subjects which are more or less distinctly brought forward in many places. The second volume is, indeed, chiefly concerned with them, though indirectly, from the point of view of folk-customs and folk-lore. The four essays included in it are entitled 'Woman as Witch,' 'Ashiepattle,' 'Kindred Group-Marriage' and 'The German Passion-Play.' Limits of space do not permit me to give an account of these, and limitations of knowledge make me incompetent to criticise them. Mr. Pearson attributes great importance to a mother-age and its customs, and emphasizes the fact that mediæval Western Christianity was a product of the Teutonic folk-spirit.

Mr. Pearson's essays and lectures are *actuel* to an unusual degree. The scientific and social problems treated by him are those most pressing for solution and those most likely to become predominent in the course of the next twenty years. It is not too much to say that these volumes should be read by every man of science.

SCIENTIFIC JOURNALS.

AMERICAN CHEMICAL JOURNAL, AUGUST.

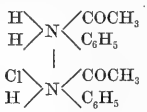
On the Oximes of Mucophenoxychloric and Mucophenoxybromic Acids: By H. B. Hill and J. A. Widtsoe. *On the Action of Aluminic Chloride and Benzol upon Mucochloryl Chloride, Mucobromyl Bromide, and the Corresponding Acids:* By H. B. Hill and F. L. Dunlap. These papers contain the results of investigations which have been carried out under Professor Hill's directions. It had been shown that mucochloric and mucobromic acids, when treated with hydroxylamine, formed normal oximes, which would indicate the presence of an aldehyde group in the acids. On the other hand, the bromanhydrides could be converted into crotonolactones by reduction, indicating an anhydride structure. The tautomerism of these acids has been the basis of the present work. Hill and Cornelison had attempted to discriminate between the two forms by a study of the action of hydroxylamine on the methylester of the acid, expecting to find that one of the forms would react readily, the other with difficulty. Although the free acids acted very quickly, the action with the methylester was very slight. When, however, one hydrogen of the acid was replaced by the phenoxy group, a substance was obtained whose ester acted readily and formed a substance identical with the ester made from the oximes by the action of methyliodide on the silver salt. The oximes and their derivatives were prepared and studied during the course of this investigation. The simplest explanation that could be offered to explain the conversion of the acids through their bromanhydrides into crotonolactones was that the acids were oxylactones. This was tested as follows: If the acid has an aldehyde structure it should, on treatment with aluminic chloride and benzol, yield an aldehyde phenylketone, while a substance belonging to the class of oxylactones should form a dichlorphenylcrotonic acid. The latter product was, in fact, the one obtained, and the authors consider the evidence sufficient to warrant the conclusion that the acid and its chloranhydride have the lactone structure.

On Certain Derivatives of Brommaleic and Chlormaleic Acid-Aldehydes: By H. B. Hill and E. T. Allen. The authors repeated the experiments of Limpricht which led to the formation of an acid-aldehyde of fumaric acid; but were unable to isolate any crystalline compound. The viscous liquid which they obtained had, however, the properties of an aldehyde. In attempts to prepare some derivative of this they obtained a product which they showed to be brommaleïc acid aldoxime. As this substance had not been previously prepared, its properties and many of its derivatives were studied. All attempts to prepare the acid itself failed. The corresponding chlorine compound can be made by the action of chlorine upon pyromucic acid.

Several interesting transformations were also studied.

On the Absorption of Oxygen by Tetrabromfurfuran: By H. A. TORREY. Although α-dibromfurfuran is readily oxidized by exposure to the air, tetrabromfurfuran, which likewise contains two bromine atoms in the α-position, undergoes no change under like conditions. Exposure to direct sunlight, however, produces a change which the author has shown to be due to oxidation. The product formed was shown to be dibrommaleyl bromide and the conditions most favorable for the action were studied.

On Halogen Addition-Products of the Anilides: By H. L. WHEELER, B. BARNES and J. H. PRATT. The authors have continued their work on the perhalides and compared them, as regards their crystallographic form, with the alkali perhalides. They found, however, that the perhalides of the anilides were not analogous in crystal form, and other facts also showed that the compounds from which the perhalides were prepared were not, as was supposed, substituted ammonium compounds. All these are derived from two molecules of an anilide with one of a halogen acid. Several structural formulas are suggested as theoretically possible; but they consider the evidence to favor the diammonium structure of which the following is an example:



A number of perhalides were prepared and their properties studied, both from a chemical and physical standpoint.

On the Permeation of Hot Platinum by Gases: By WYATT W. RANDALL. After giving a historical résumé of the work that has a bearing on this point the author gives the results observed in the preparation of pure hydrogen. The form of apparatus used, in which every possible precaution was taken to insure the purity of the hydrogen before it came in contact with the hot platinum, is given in detail. In these experiments the passage of the hydrogen was very slow as compared with the results obtained by Graham. Under the same conditions oxygen and nitrogen do not permeate the tube, and experiments made with marsh gas, which has a density only half that of oxygen, have so far given negative results. The hydrogen was examined spectroscopically, as this method was the most delicate for detecting the presence of other gases. The photographs all showed the so-called 'compound' spectrum. Whether this is evidence of some contamination can not yet be decided, as the evidence is not sufficient to settle this point.

On Some Malonic Acid Derivatives: By R. S. CURTISS. When ethylchlormalonate is treated with cold alcoholic ammonia a compound is formed in which the chlorine atom remains intact; whereas if the action is carried on in a sealed tube at 140° the chlorine atom is displaced. On treating ethylbrommalonate with aniline, a weaker base than ammonia, he obtained, as he expected, a compound in which the bromine was substituted, without affecting the carbethoxyl group. By treating ethylanilidomalonate with mercuric oxide he obtained ethyldianilidomalonate and also studied the action of sodium ethylate on ethyldibrommalonate.

The Action of Nitric Acid on Triphenylmethane: By E. S. SMITH. In attempting to prepare trinitrotriphenylmethane by the action of fuming nitric acid on triphenylmethane the author obtained in one case a compound which was shown to be triphenylcarbinol. This substance is usually made by the use of chromic acid as the oxidizing agent, but in the case mentioned the nitric acid acted in a similar manner.

THE TORONTO MEETING OF THE BRITISH ASSOCIATION.

THE British Association decided to meet in Montreal in 1884, with some hesitation, but after the great success of that meeting an invitation presented at Oxford in 1894, urging the Association to meet at Toronto in 1897, was accepted by the general committee with unanimity. Elaborate arrangements were made by the Dominion, by the City of Toronto and by the University, for the reception of the Association, and steamship, railway and cable companies united to offer unusual facilities to visitors. The chairman of the local committee, Professor Macallum, was especially self sacrificing in devoting himself for more than a year to the work of arrangement. A visit of the leaders of British science to Canada is an event of no common importance for the Dominion, and the enthusiasm was this year intensified by a United States tariff law and a British Jubilee.

The members and associates in attendance at Toronto numbered somewhat over 1,300, about 400 fewer than at the Montreal meeting. SCIENCE has already published an article by Professor Macallum giving a list of the more distinguished British and Continental men of science who expected to attend, and with a few exceptions, such as Lord Rayleigh, they were present. Men of science from the United States were well represented. The attendance from Great Britain, the Continent, Canada and the United States can best be indicated by giving the officers and committees of the various sections, which were as follows:

SECTION A.—MATHEMATICAL AND PHYSICAL SCIENCE.

President: Prof. A. R. Forsyth, D. Sc., F.R. S.

Vice-Presidents: Prof. W. E. Ayrton, F. R. S.; Prof. G. C. Foster, F. R. S.; Prof. Henrici, F. R. S.; Dr. G. W. Hill; Prof. A. Johnson, Lord Kelvin, F. R. S.; Prof. O. J. Lodge, F. R. S.; President Loudon; Prof. A. A. Michelson; Prof. S. Newcomb.

Secretaries: Prof. W. H. Heaton, M. A.; (*Recorder*); J. C. Glashan; J. L. Howard, D. Sc.; Prof. J. C. McLennan, B. A.; Prof. J. G. McGregor, D. Sc.

Committee: Prof. W. G. Adams, F. R. S.; Prof. A. Baker; Prof. G. F. Barker; Prof. Carl Barus; Prof. F. Bedell; Prof. W. W. Beman; Dr. J. T. Bottomley, F. R. S.; Prof. C. V. Boys, F. R. S.; Prof. Braun; Prof. O. Bolza; Prof. Eddy; Prof. H. L. Callendar, F. R. S.; Prof. Carhart; Prof. Cross; Prof. A. T. DeLeury; Prof. Ewing, F. R. S.; Prof. Fitzgerald, F. R. S.; Prof. T. Gray; Prof. Greenhill, F. R. S.; Dr. Harris Hancock; Prof. T. Holgate; Prof. W. H. H. Hudson; J. Hopkinson; Prof. J. V. Jones, F. R. S.; Prof. Hale; Prof. W. J. Loudon; Dr. D. MacAlister; Prof. A. Macfarlane; Major McMahon, F. R. S.; Dr. E. McClintock; Prof. McKay; Dr. M. Maclean; Prof. H. McLeod, F. R. S.; Prof. H. Maschke; Prof. E. Merritt; Prof. W. H. Metzler; Dr. Morley; Prof. Nichols; Prof. S. Newcomb; Prof. Newson; J. A. Paterson; Prof. J. Perry, F. R. S.; W. A. Price; Prof. Rücker, F. R. S.; Prof. C. Runge; Dr. Van Rijckevorsel; Prof. A. W. Scott; R. F. Stupart; Prof. S. P. Thompson, F. R. S.; A. E. Western; E. T. Whittaker; Prof. Woodward; Prof. Ziwet.

SECTION B.—CHEMISTRY.

President: Prof. W. Ramsay, F. R. S.

Vice-Presidents: Prof. G. F. Barker; Prof. F. W. Clarke; Prof. H. B. Dixon, F. R. S.; W. R. Dunstan, F. R. S.; Prof. B. J. Harrington; Prof. E. W. Morley; Prof. W. H. Pike; Prof. I. Remsen; Prof. W. C. Roberts-Austen, F. R. S.

Secretaries: Prof. W. H. Ellis; Arthur Harden (*Recorder*); Charles A. Kohn; Prof. R. F. Ruttan.

Committee: Prof. W. W. Andrews; Prof. H. E. Armstrong, F. R. S.; Prof. B. Brauner; Prof. R. A. Fessenden; Prof. C. Le Neve Foster, F. R. S.; Prof. P. C. Freer; Prof. W. L. Goodwin; A. Vernon Harcourt, F. R. S.; O. S. James; F. B. Kenrick; Prof. A. R. Leeds; Prof. Loeb; Prof. H. McLeod, F. R. S.; Prof. Meldola, F. R. S., Prof. Meslans; W. L. Miller; Prof. J. U. Nef; Prof. W. A. Noyes; H. Ramage; W. W. Randall; Prof. T. W. Richards; F. T. Shutt; F. J. Smale; Prof. A. Smith; A. Stansfield; W. M. Watts; Prof. W. C. Williams; Prof. H. W. Wylie.

SECTION C.—GEOLOGY.

President: Dr. G. M. Dawson, C. M. G., F. R. S.

Vice-Presidents: Dr. W. T. Blanford, F. R. S.; Prof. C. LeNeve Foster, D. Sc., F. R. S.; Prof. G. K. Gilbert; Prof. H. Alleyne Nicholson, F. R. S.

Secretaries: Prof. A. P. Coleman, M. A., Ph. D.; G. W. Lamplugh; Prof. H. A. Miers, F. R. S. (*Recorder*).

Committee: Prof. F. D. Adams; Dr. H. M. Ami; The Rt. Hon. James Bryce, M. P.; Prof. T. C. Chamberlin; Dr. F. W. Clarke; Dr. W. H. Dall; Sir J. Evans, K. C. B., D. C. L., F. R. S.; Dr. H. O. Forbes; W. F. Ferrier, B. A. Sc.; Prof. J. B. Harrington; J. Hopkinson; Prof. L. C. Miall, F. R. S.; Prof. John Milne, F. R. S.; J. L. Myres; Prof. Albrecht Penck; Prof. E. B. Poulton, F. R. S.; Dr. A. R. C. Selwyn, C. M. G., F. R. S.; Prof. J. C. Smock; Dr. J. W. Spencer; A. C. Seward, M. A.; B. B. Walker; J. W. Woodall.

SECTION D.—ZOOLOGY.

President: Prof. L. C. Miall, F. R. S.

Vice-Presidents: Prof. W. A. Herdman, D. Sc., F. R. S.; Prof. R. Meldola, F. R. S.; Prof. E. B. Poulton, D. C. L., F. R. S.; Prof. R. Ramsay Wright.

Secretaries: Walter Garstang, M. A.; Prof. E. E. Prince, B. A.; W. E. Hoyle, M. A. (*Recorder*).

Committee: Senator G. W. Allan; Prof. Mark Baldwin; Dr. T. Bethune; Dr. Anton Dohrn; Dr. Eigenmann; Dr. Theodore Gill; Prof. Gustave Gilson; Dr. L. O. Howard; Prof. Malcolm Laurie; Prof. J. P. McMurrich; Prof. C. S. Minot; Prof. C. Lloyd Morgan; Prof. E. S. Morse; Prof. H. F. Osborn; J. F. Whiteaves.

SECTION E.—GEOGRAPHY.

President: J. Scott Keltie, LL. D.

Vice-Presidents: Dr. Burwash; E. G. Ravenstein; Prof. A. Penck; F. C. Selous; Coutts Trotter.

Secretaries: Colonel F. Bailey; Dr. H. R. Mill (*Recorder*); Captain Deville; J. B. Tyrrell.

Committee: Marcus Baker; W. M. Beaufort; Dr. W. T. Blanford, F. R. S.; Rt. Hon. James Bryce; Prof. W. M. Davis; Prof. R. E. Dodge; Dr. H. O. Forbes; General A. W. Greely; Otto J. Klotz; Prince Krapotkin; Prof. John Milne, F. R. S.; Prof. Willis L. Moore; E. Delmar Morgan; Sir G. S. Robertson, K. C. S. I.; A. Laurence Rotch; Sir John Swinburne, Bart; J. White.

SECTION F.—ECONOMICS AND STATISTICS.

President: Prof. E. C. K. Gonner, M. A.

Vice-Presidents: Prof. W. Clark, M. A., LL. D.; Prof. J. Mavor; The Hon. Sir C. W. Freemantle, K. C. B.

Secretaries: E. Cannan, M. A.; Prof. A. Shortt, M. A.; Henry Higgs, LL. B. (*Recorder*).

Committee: Archibald Blue; The Rt. Hon. James Bryce, M. P.; R. E. Ely; Sir Malcolm Fraser; Prof.

N. P. Gilman; Prof. A. T. Hadley; J. A. McLean; W. H. Moore; Prof. Simon Newcomb; Prof. Goldwin Smith; B. E. Walker; S. M. Wickett.

SECTION G.—MECHANICAL SCIENCE.

President: G. F. Deacon, M. Inst. C. E.

Vice-Presidents: Prof. W. E. Ayrton, F. R. S.; Prof. H.T. Bovey, M. A.; Prof. John Galbraith, M.A.; Prof. G. Lanza; Prof. W. C. Unwin, F. R. S.

Secretaries: Prof. T. Hudson Beare, F.R.S.E. (*Recorder*); Prof. Dupuis; W. A. Price, M.A.; Prof. Callendar, M.A., F.R.S.

Committee: J. G. W. Aldridge; Prof. Baily; J. T. Bottomley; Bryan Donkin; Prof. R. C. Carpenter; E. K. Clark; J. Coates; Prof. Ewing, F.R.S.; Prof. Vernon Harcourt; C. Hawksley; W. T. Jenning; Lord Kelvin, G.C.V.O., F.R.S.; H. S. Maxim; Prof. Perry, F.R.S.; Prof. S. P. Thompson, F.R.S; W. G. Walker; Major-General Webber, C.B., R.E.

SECTION H.—ANTHROPOLOGY.

President: Prof. Sir W. Turner, M.D., LL.D., F.R.S.

Vice-Presidents: E.W. Brabrook, C.B., Pres. Anthr. Inst.; Prof. A. Macalister, M.D., F.R.S.; R. Munro, M.D., F.R.S.E.; Dr. W J McGee; Prof. F. W. Putnam, D.Sc.

Secretaries: A. F. Chamberlain, Ph.D.; H. O. Forbes, LL.D.; Prof. A. C. Haddon, D.Sc.; J. L. Myres, M.A., F.S.A. (*Recorder*).

Committee: David Boyle; Dr. G. M. Dawson, C.M.G.; F. T. Elworthy; A. F. Hunter; Prof. E. S. Morse; E. Sidney Hartland, F.S.A.; Prof. Lightner Witmer, Ph.D.

SECTION I.—PHYSIOLOGY.

President: Prof. Michael Foster, M.A., LL.D., Sec. R.S.

Vice-Presidents: Lord Lister, P.R.S.; Dr. J. S. Billings; Prof. H. P. Bowditch, M.D.; W. H. Gaskell, M.D., F.R.S.; Prof. A. B. Macallum, M.B., Ph.D.; Prof. W. Osler, M.D.; Prof. C. Richet, M.D.; Prof. A. D. Waller, M.D., F.R.S.

Secretaries: Prof. Rubert Boyce, M.B. (*Recorder*); Prof. C. S. Sherrington, M.D., F.R.S.; A. Kirschmann, Ph.D.; L. E. Shore, M.D.

Committee: Prof. Cushny; Prof. E. M. Crookshank; Prof. W. D. Halliburton; Prof. Carl Huber; Dr. K. Huerthle; Dr. D. McAlister; Dr. J. H. Kellogg; Prof. F. S. Lee; Prof. J. Loeb; Prof. W. P. Lombard; Prof. Wesley Mills; J. J. Mackenzie; Dr. Noel Paton; Prof. W. T. Porter; Prof. Waymouth Reid; Prof. Anderson Stuart; Prof. G. N. Stewart; Prof. W. H. Thompson.

SECTION K.—BOTANY.

President: Prof. Marshall Ward, Sc.D., F.R.S.

Vice-Presidents: Prof. D. P. Penhallow, M.A.; Prof. Farlow, M.D., LL.D.; Prof. F. O. Bower, Sc.D., F.R.S.

Secretaries: E. C. Jeffrey, B.A.; Prof. Bretland Farmer, M.A.; A. C. Seward, M.A.; Prof. F. E. Weiss, B.Sc. (*Recorder*).

Committee: Prof. Arthur; Prof. Atkinson; Prof. Barnes; Prof. Bessey; Prof. Britton; Prof. Campbell; Prof. Coulter; Dr. Fletcher; Dr. Galloway; Prof. Reynolds Green; Prof. Greene; Arthur Lister; Prof. MacDougal; Prof. Magnus; Dr. Saunders; Harold Wager; H. J. Webber.

Nearly all these scientific leaders and many others were present at Toronto when the Association was received by the civic authorities, at four o'clock on the afternoon of Wednesday, August 18th. Addresses of welcome were made by Lord Aberdeen, the Governor-General, and by the Mayor of the city. Replies were made by the retiring President of the Association, Lord Lister, by the incoming President, Sir John Evans and by Lord Kelvin. The Premier of the Province and the Minister of Education also made remarks. In the evening Lord Lister resigned the presidency to Sir John Evans, who gave the address already published in SCIENCE (page 269). Remarks thanking the President for his address were made by Lord Aberdeen, Lord Kelvin and Mayor Shaw.

Other general meetings of the Association were held to listen to the evening addresses by Professor W. C. Roberts-Austen and by Professor J. Milne. Professor Austen, on August 20th, lectured on 'Canada's Metals'. He reviewed the discovery and prospects of Canadian gold fields, illustrating the subject by a series of photographs, and called special attention to the nickel deposits of the Dominion. Illustrations were also shown of the speaker's interesting experiments on the splash of metals, and a demonstration was given showing on the screen the action of the electric furnace. Professor Milne, on Monday evening, lectured on a subject in which he is the leading authority, 'Earthquakes and Vol-

canoes.' He discussed especially the causes leading to the display of seismic and volcanic activity and the benefits to be derived from studying the phenomena. Dr. H. O. Forbes gave, on Saturday evening, the usual lecture to artisans, taking as his subject 'Borneo.' Meetings were also held for the conferring of degrees on several of the prominent members both by Toronto University and by Trinity College.

The arrangements for social intercourse and entertainment were numerous and attractive. A reception was given by the Governor-General and the Countess of Aberdeen on Thursday evening; there was a conversatzione in the University building on Tuesday evening and a banquet in honor of Lord Kelvin, Lord Lister and Sir John Evans on Wednesday evening. There were garden parties daily in the afternoons and many luncheons and dinners. Excursions were made on Saturday to Niagara Falls and in other directions, and for the Thursday following the meeting excursions were arranged to Montreal, Ottawa and elsewhere. Finally elaborate excursions were planned under the most favorable conditions to the maritime provinces and to Manitoba and the Pacific coast.

The business of the Association is transacted by the General Committee, chiefly on advice of the Council. This year part of the arrangements, including the election of officers for next year, were deferred until an autumn meeting in Great Britain. Professor Roberts-Austen was made General Secretary in succession to Mr. Vernon Harcourt, and in the room of the five members of the Council who retired there were elected F. Darwin, Esq., Sir C. W. Freemantle, Professor W. D. Halliburton, Professor S. P. Thompson and Sir W. H. White. Dr. F. Kohlrausch, Berlin; Dr. Van Rejckevorsel, Rotterdam, and Professor E. Zacharias, Hamburg, were made corresponding members.

The report of the Council adopted by the General Committee contained reports of two important committees appointed at the Liverpool meeting. The committee appointed to bring before the government the question of the establishment of a national physical laboratory has been in so far successful that the Treasury is taking the matter into consideration and has appointed a committee to report on such a laboratory.

The committee appointed to urge upon the government the importance of establishing a Bureau of Ethnology for Greater Britain, consisting of the President and General Officers, with Sir John Evans, Sir John Lubbock, Mr. C. H. Read and Professor Tylor, made the following report:

A central establishment in England, to which would come information with regard to the habits, beliefs and methods of government of the primitive peoples now existing would be of great service to science and of no inconsiderable utility to the government.

1. The efforts of the various societies which have, during the last twenty years, devoted themselves to collecting and publishing ethnological information have necessarily produced somewhat unequal, and therefore unsatisfactory, results. Such societies had, of course, to depend upon the reports of explorers, who usually travelled for another purpose than that in which the societies were interested; and such reports were naturally unsystematic, the observers being mostly untrained in the science. Again, whole regions would be unrepresented in the transactions of the societies, perhaps from the absence of the usual attractions of travellers, *e.g.*, big game or mineral riches. This has been to some extent corrected, at least as to the systematic nature of the reports, by the publication of 'Anthropological Notes and Queries,' by the Anthropological Institute, with the help of the British Association.

If it be admitted that the study of the human race is an important branch of science, no further argument is needed to commend the gathering of facts with regard to the conditions under which aboriginal races now live, and if this work is worth doing, it should be done without delay. With the exception, perhaps, of the negro, it would seem that none of the lower races are capable of living side by side with whites. The usual result of such contact is demoralization, physical decline and steady diminution of numbers;

in the case of the Tasmanians, entire disappearance. Such will probably soon be the fate of the Maories, the Andamanese, the North American Indians and the blacks of Australia. While these exist it is possible to preserve their traditions and folk-lore and to record their habits of life, their arts and the like, and such direct evidence is necessarily more valuable than accounts filtered through the recollection of the most intelligent white man.

It is scarcely necessary to enlarge upon this point, as no one will seriously question the value to science of such information. But it does seem necessary to urge that no time be lost.

2. As to the benefit, to the government, of these inquiries, the history of our relations with native tribes in India and the colonies is rich in examples. No one who has read of the ways of the African can doubt that a thorough study of his character, his beliefs and superstitions is a necessity for those who have to deal with him. And what is true of the natives of Africa is also true, in a greater or less degree, of all uncivilized races. Their ideas of common things and common acts are so radically different from those of civilized man that it is impossible for him to understand them without a special training.

Even in dealing with the highly civilized natives of India it is most necessary that an inquirer should be familiar with their religion and with the racial prejudices which the natives of India possess in common with other civilized nations.

A training in knowledge of native habits is now gone through by our officers, traders and missionaries on the spot; and by experience—sometimes dearly bought—they, after many failures, learn how to deal with the natives. By the establishment of such a bureau as is here advocated much might be done to train our officers before they go out, as is now done by the Dutch government, who have a handbook and a regular course of instruction as to life, laws, religion, etc., of the inhabitants of the Dutch Indies. The experience thus gained would then mature rapidly, and they would become valuable servants to the state more quickly.

The collecting of the necessary information for the Bureau could be done with but little expense and with a very small staff only, if the scheme were recognized and forwarded by the government. If instructions were issued, for instance, by the Colonial Office, the Foreign Office, the Admiralty, and the Intelligence Branch of the War Office, to the officers acting under each of these departments, not only that they were at liberty to conduct these inquiries, but that credit would be given to them officially for good work in this direction, there is little doubt that many observers qualified by their previous training would at once put themselves and their leisure at the disposal of the Bureau.

The Bureau itself, the central office, would be of necessity in London—in no other place could it properly serve its purpose—and preferably for the sake of economy and official control, it should be under the administration of some existing government office. But the various interests involved make it somewhat difficult to recommend where it should be placed. The Colonial Office would obviously present some advantages. The British Museum has been suggested, with good reason, and there appears to be no insuperable difficulty if the Trustees are willing to undertake the responsibility of controlling such a department.

The staff would not be numerous. A Director accustomed to deal with ethnological matter would necessarily direct the conduct of the inquiries, and until the material assumed large proportions two or three clerks would probably suffice. If the value of the results were considered to justify it, the increase of the area of operations over the world would probably call for additional assistance after the Bureau had been at work for a few years.

The Bureau of Ethnology in the United States aims chiefly at publishing its reports, but its area is limited to America. The scope of the present proposal is so much wider that the Committee think it better not to deal with the question of publication at present.

If this report be adopted by the Council it will be necessary to approach the government and impress upon them the importance of having such an organization for carrying out these recommendations. For this purpose a deputation should be appointed, and it would be well to invite the Council of the Anthropological Institute to appoint two members."

The Council resolved that the Trustees of the British Museum be requested to consider whether they could allow the proposed Bureau to be established in connection with the Museum; and if they are unable to sanction this proposal, that the authorities of the Imperial Institute be requested to undertake its establishment. The matter is now under the consideration of the Trustees of the British Museum.

The Report of the Corresponding Societies Committee for the past year, together with the list of the corresponding societies and the titles of the more important papers, and especially those referring to local

scientific investigations, published by those societies during the year ending June 1, 1897, was received.

One of the most important functions of the Association is represented by the work of its committees. In addition to the three reports to the Council many very valuable reports were presented at Toronto before the sections, which will be noticed in special articles on the work of the sections to be published in subsequent issues of SCIENCE.

THE AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

*LONG RANGE TEMPERATURE AND PRESSURE VARIABLES IN PHYSICS.**

METHODS OF PYROMETRY.

THE endeavor to provide suitable apparatus for high temperature measurement is one of long standing. The student of the subject is fairly overwhelmed with the variety of devices which have been proposed. There are few phenomena in physics which have not in some way or other been impressed into pyrometric service, often indeed by methods of exquisite physical torture. I cannot, of course, even advert to many of these this afternoon, as my purpose will have to be restricted to such devices as have usefully survived. Thus a whole group of 'intrinsic thermoscopes,' as Lord Kelvin calls them — apparatus in which some property of the substance is singled out for measurement—will be overlooked. Pyrometry will some day receive substantial aid from the phenomena of solid thermal expansion, dear to the hearts of old Wedgewood, of Professor Daniells, of the citoyen Guyton-Morveau, and recently to Professors Nichols, Joly and others; but even the 'meldometer,' which has received Ramsay's encouragement and recent heroic attempts to measure the expansion of platinum, have not yet entered the arena to stay.* The same may be said of vapor pressure, ebullition and certain dissociations, of which the former is entirely too liberal in dispensing pressure, and the latter too negligent in readjusting it. Little has been done with heat conduction regarded as subservient to the measurement of high temperatures; little with color and the spectrum, even though Draper and Langley in this country and many others abroad have paid tribute; little with polarization. The wave-length of sound has told Cagniard Latour and our own A. M. Mayer much about high temperature, but it did not tell them enough.

Throughout the history of pyrometry, *fusion* seems to have come forward for journeyman duty. What is more convenient than to find whether the degree of red heat is too low or too high from the fusion of prepared alloys. As far back as 1828 Prinsep, aware of the golden opportunity, with his golden air thermometer determined the melting point of some equally precious alloys of gold, silver and platinum, and determined them very well. Other alloys were afterwards substituted and graded mixtures made of quartz, chalk, kaolin and feldspar for the purpose. Efforts to obtain more accurate values are due to Becquerel; but the absolute values most widely used until quite recently, namely, the melting points of silver (958°), gold (1035°), copper (1054°), palladium (1500°), platinum (1775°), iridium (1950°), are due to the researches of Violle.

Interest in high temperature fusions has of recent date rather increased than abated. The demand for more accurate data has been met by the Reichsanstalt, and we have now a set of values for silver, copper, gold, nickel, palladium and platinum in terms of

* Address by Professor Carl Barus, Vice-President and Chairman of Section B (Physics).

* Noteworthy attempts to replace mercury by a liquid potassio-sodium alloy in glass thermometers are among the novelties.

the air thermometer standard of that institution. Data have also been supplied by Callendar. Among these values there is as yet considerable confusion and the end is not yet. Long ago I suspected that the Violle melting points were probably too low, whereas the assumed zinc boiling point is probably too high. This surmise has been partially borne out by the Reichsanstalt, though Le Chatelier even now prefers Violle's values.*

Thermoscopes based on a *specific heat* have an advantage over fusion thermoscopes in not being discontinuous. They are quite as 'intrinsic' and much less convenient in practice. Guyton-Morveau, at the beginning of the century, pointed out the pyrometer importance of specific heat, and a host of observers followed him. But the critical discussion of the subject is due to Pouillet (1836), who determined the thermal capacity of platinum between 0 and 1200° absolutely, and found a value so nearly constant as to place this method of pyrometry in a very favorable light. Other observers followed with new data, and the bulk of our knowledge to-day is again due to Violle. Violle used Deville and Troost's exhaustion air thermometer and determined the law of variations of specific heat and temperature throughout a large pyrometric interval, with a number of metals, silver, gold, copper, palladium, platinum, iridium, among them. It was by prolonging this law as far as fusion that the melting points of the metals, to which I have already alluded, were obtained. This verges on extrapolation, but it is not extrapolation gone mad.

The importance of calometric high temperature measurement has recently been accentuated in connection with the remarkable high temperature accomplishments of Moissan. Furnace temperatures in the case of such technological operations as are used in connection with iron, glass and porcelain manufacture rarely exceed 1,400°, except perhaps in the Bessemer process, where the temperatures are wont to exceed 1,600° and even reach 2,000°. In Moissan's furnace, which is essentially an electric arc enclosed by non-conducting lime, a totally new order of high temperatures is impressed. There was thus a call for at least an approximate measurement of their values, which was answered by Violle, assuming that the specific heat of carbon above 1,000° approaches a limit. The sufficiency of this hypothesis is not unchallenged, however; for instance, Le Chatelier finds that, up to 1,000°, the specific heat of carbon continually increases, having no certain limit. Admitting Violle's results, Moissan's furnace temperatures exceed 2,000° even at 30 amperes 55 volts; at 360 amperes and 70 volts tin and zinc oxides melt and boil; they exceed 3,000° at 500 amperes and 70 volts, where lime melts, and often boils. Moissan, however, went as far as 1,000 amperes at 50 volts.

The striking novelty of Moissan's work is rather of chemical interest, and a large part of it is so fresh in our memory that, in view of Moissan's forthcoming book,* I need merely glance at it. A range of fusibilities, among which platinum lies lowest, while chromium, molybdenum, uranium, tungsten, vanadium, follow in order, and of ebullitions beginning with silica and zinc oxide, is rather breath-taking. Finally, his structural investigations on the occurrence of carbon, and his long series of carbides, many of them commercially valuable, have staggered even the sensational press.

Leaving other intrinsic thermoscopes for the moment, I will ask your attention in

* The following table contains a brief summary :

Ag.	(Violle) 954°	(Barus) 986°–985°	(Callendar) 982°	(H.&W.) 971°
Au.	1045°	1091°–1093°	1037°	1072°
Cu.	1054°	1096°–1097°		1082°
Ni.	——	1476°–1517°		1484°
Pd.	1500°	1585°–1643°		1587°
Pt.	1775°	1757°–1855°		1780°

* Le four électrique, par Henri Moissan ; Paris, Steinheil.

this place to the development of the only fruitful method of absolute pyrometry which has yet been devised. I refer, of course, to the gas thermometer, or, in other words, to the manometric methods of measuring the thermal expansion of gases. Efforts have, indeed, been made to use gaseous viscosity for absolute high temperature work. It has been definitely pointed out, inasmuch as viscosity in gases is independent of pressure, while both viscosity and volume increase with temperature, that the transpiration rates of gases through capillary tubes of platinum glazed externally would necessarily be an exceedingly sensitive criterion of the variation of high temperatures. The small volume of the transpiration pyrometer as compared with the clumsy fragile bulb and appurtenances of the air thermometer is further to the point. But modern kinetics has as yet failed to fathom the law of variation of viscosity with temperature, and even the researches of O. E. Meyer in this direction do not seem to have quite touched bottom. Gaseous transpiration pyrometry is thus still much in the air, surveying the horizon of a glorious future.

Returning from this digression to the air thermometer, we find the first thoroughgoing piece of high temperature work carried out by Prinsep (1829), by the aid of a reservoir of pure gold to which I have already alluded. Prinsep's manometer was filled with olive oil, and the volume issuing at constant pressures was found by the balance. In view of the pure olive oil, probably available in 1829, these experiments must have been comfortably appetizing, and I dare say Prinsep's good humor in the matter may have contributed to the remarkable excellence of his results. Prinsep's researches were not superseded until Pouillet, in 1836, published his paper on pyrometry. Pouillet constructed an air thermometer bulb of platinum and was thus able to reach the farthest pyrometric north of the day and long after. His results are many sided; they contain the first definite data in radiation pyrometry and in calometric pyrometry. His constant pressure manometer, afterwards further perfected by Regnault, is the best apparatus for the purpose to-day. Pouillet did not suspect, indeed he remained quite unaware of, the permeability of platinum to furnace gases; perhaps for this and other reasons he failed to detect the thermo-electric anomalies in the platinum-iron couple which he so carefully calibrated.

It was thus a great step in advance when Deville and Troost long after replaced platinum by glazed porcelain, availing themselves (1857–60) of Dumas' famous vapor density method for measuring temperature. Unfortunately for the rapid progress of pyrometry, Deville and Troost used iodine vapor in their bulbs, a heavy gas indeed, but a gas, as was afterwards found, whose low temperature molecule dissociates at higher temperatures. Thus they unwittingly committed an even greater error than Pouillet in gliding over permeable platinum, and their data for the boiling points of zinc and of cadmium were about 100° too high. In fact, these results were challenged not long after by Becquerel (1863), who had fallen heir to Pouillet's platinum air thermometer, had used it to calibrate a platinum-palladium thermocouple of his own, and had found data for the boiling points of zinc and cadmium upwards of 110° below those of Deville and Troost. I cannot here enter upon the discussion which thereafter arose between these active observers further than to state that in the course of it both parties frequently repeated their measurements (Becquerel even substituting a porcelain bulb for Pouillet's thermometer) without removing the decrepancy between their values.

Later researches have decided in favor

of Becquerel's results, and his original research, with its applications to fusion, to radiation, to thermo-electrics, etc., is one of the noteworthy accomplishments in the history of pyrometry. Nevertheless, it must not be forgotten that to the investigation of Deville and Troost our knowledge of the perviousness of iron, platinum and other metals to gases is due. We are also indebted to Deville for the great discovery of dissociation, the very phenomenon which he was here so loth to acknowledge. This is the case of a man stumbling in his own footprints. Victor Meyer was, I believe, the first to point out the probable dissociability of the iodine molecule, suggesting a fruitful subject of research which has since been extended to many other molecules.

In 1863 Deville and Troost began a new series of high temperature researches, the feature of which is the perfected form of porcelain bulb. This was a hollow sphere and long capillary stem adapted for use with Regnault's standard air thermometer. Great difficulties were encountered in the endeavor to glaze the bulbs within. They were finally overcome by making bulb and stem separately and then soldering them together with feldspar before the oxy-hydrogen blow pipe. Elaborate measurements on the thermal expansion of Bayeux porcelain accompany these researches which, undertaken together with M. Gosse of the Bayeux works, occupied them intermittently for about seven years. A full summary of their data did not appear, however, until 1880, when, together with a new vacuum method of high temperature air thermometry, they communicated the results of twenty-seven measurements on the boiling point of zinc. Their new results are in good accord with the data of Becquerel already cited and the more recent results of Violle and others for the same landmark in the region of high temperatures. Measurements between 0° and 1500° had thus reached a degree of precision of about 15° in 1000°.

The further development of pyrometry took a somewhat different direction. Regnault (1861) had already made use of a displacement method, in which the measuring gas is removed bodily into the measuring apparatus by an absorbable gas. But the method was independently revived by Professor Crafts, of the Boston Institute of Technology. These methods are not of especial excellence below 1500° ; but above that temperature, when most solids tend to become viscous, their importance increases (as Crafts duly pointed out) in proportion to the rapidity with which the measuring operations can be completed. One or two minutes may suffice and different gases may be tested consecutively. It is in this way that Victor Meyer and his pupils, after demonstrating the dissociation of iodine and chlorine molecules, succeeded in penetrating quantitatively to very much less accessible heights of temperature. A particular desideratum was a rigid test as to the stability of the molecule of the standard measuring gases (oxygen, hydrogen, nitrogen). The results were favorable, inasmuch as for these and for many gases like CO_2, SO_2, HCl, Hg, etc., the expansions obtained were linear functions of each other.

In their final work, temperatures as high as 1700° were reached, the air thermometer for this purpose being tubular in form, consisting of very refractory fire clay with an interior and exterior lining of platinum and with two end tubulures of platinum for influx and efflux of gases. Among many results of great chemical interest their researches showed that metallic vapors, phosphorus, sulphur, etc., at high temperatures tend to pass into the monatomic or the diatomic molecular structure.

Sometime after (1887) a series of experiments furthering the line of research of

Deville and Troost were made, with a geologic aim in view, in the laboratory of the U. S. Geological Survey. Finally, porcelain air thermometry was taken up with great vigor by the Reichsanstalt. These results, due to Holborn and Wien, are now almost exclusively quoted and carry the stamp of the great institution from which they emanated. They have been wisely made commercially available by the deposition, with Heräus, in Hanau (Germany), of a platinum rhodium alloy definitely calibrated for a temperature range of 1400°.

Apart from this, these researches contain no essential novelty, except, perhaps, a more detailed attempt to investigate the stem error of the thermometer bulb; their procedure otherwise is identical with the method developed in this country. I am not, therefore, inclined to yield to it the unhesitating deference which has become customary. There can be no doubt, in view of the splendid facilities due to the cooperation of the Royal Prussian porcelain works—facilities which those who have been baffled by porcelain technology, or have had to coax unwilling manufacturers into reluctant compliance, will appreciate—that the data of the Reichsanstalt will eventually be standard. For the present, however, I should be more impressed by some sterling novelty either in the direction of a larger range of measurement or of method. Conceding that an accuracy of 5° at 1000° has been reached, all results above 1500° remain none the less subject to increasingly hazardous surmise.

A beautiful method of absolute thermometry, albeit as yet only partially developed, is due to Töpler. In this the densities of communicating columns of gas are compared very much as in Dulong and Arago's classical methods for liquids, by the gravitation pressures which correspond to these unequally hot columns. To accomplish such extremely fine pressure measurement, Töpler invented the 'Druck libelle,' an inversion, as it were, of the common level, in which, therefore, the motion of the bubble (or of a thread of liquid) indicates a change of pressure conditioned by the invariable horizontality of the instrument.

The development of the practical forms of continuous intrinsic thermoscopes (the *radiation*, the *thermo-electric* and the electric *resistance* methods) went, more or less, hand in hand with the development of the air-thermometer, although the latter is decidedly the more recent. Aside from pioneering experiments of Müller (1858) and others, the well-known Siemens resistance pyrometer (1871) was the first instrument in the field. It was based upon data obtained from platinum, copper and iron by the calometric method of calibration. This instrument has been remarkably perfected by Callendar and Griffiths, using specially pure platinum calibrated by comparison with the air-thermometer as far as about 600°. Notwithstanding these improvements, the resistance pyrometer is inferior, in my judgment, to the thermo-electric pyrometer, from the greater bulk and fragility of the exposed parts and the tendency of platinum to disgregate or waste itself gradually at high temperatures. Its upper limit of temperature measurement is thus limited; for, even if the difficulty of selecting suitable terminals for the coil is set aside, the difficulty of finding an insulator at very high temperatures would remain. According to Holborn and Wien resistance is seriously subject to the influence of furnace gases, and permanence of the low temperature constants does not imply a like permanence of the high temperature constants of the metal.

Radiation pyrometry, curiously enough, is the most venerable method within the whole scope of the subject. It was introduced by Newton (1701) in his *scala graduum caloris* in connection with his well-

known law of cooling. Not to mention minor workers, it was successively attacked and revived in most of the noteworthy high temperature investigations. Pouillet and Draper have studied it; Becquerel, Crova, Violle, Le Chatelier, Langley, Nichols, Paschen and others have advanced it. It remains to-day the most promising as well as puzzlingly fascinating subject for pyrometric research. One needs merely advert to its broad scope in relation to the temperature of the heavenly bodies to acknowledge this. Here I can only allude to Becquerel's principle that the radiation of opaque bodies is spectrometrically alike at the same temperature, a result which has Crova's more recent assent; to Violle's photometric measurements of the total emission of platinum; to the more recent work in the same direction of Violle and Le Chatelier, in which consistent results were obtained for oxide of iron and platinum as far as 1500° to 1700°; to Stefan's law as proved by Boltzmann, and the variety of discussion it has elicited; to H. F. Weber's collateral equation; to the Johns Hopkins measurements, etc. Another school of observers, including Langley, Paschen and others, has undertaken the promising but much more laborious method of bolometric measurement of the distribution of spectrum energy in its relation to temperature. Without doubt, however, the whole subject is yet *in primis rudimentis;* the results are confessedly 'intrinsic.' Indeed, vagueness in the nature of the radiating source lowers with sufficiently threatening aspect to chill the fondest hopes. When one is told by Violle working on Mont Blanc that the temperature of the sun is 2500°; thereupon by Rossetti that it is 9965°, by Le Chatelier that it is at least 7600°, by Paschen that it is below 5000°, by Wilson and Gray that it is 8000°, etc., one wisely concludes that more may yet be learned about it. Our sympathies naturally go with those who, like Lummer and Wien and the Johns Hopkins people, are beginning fundamentally with the search for an absolutely black body. Less superstructure and more sub-cellar is, perhaps, the watchword in radiation pyrometry.

Turning, now, to the last and most important of the methods of practical pyrometry, we find a curiously meandering evolution apparent. I have already indicated that Pouillet (1836) was the first to complete a legitimate piece of calibration work. Pouillet might have condemned the method, but for some reason Tait's thermoelectric anomalies of red-hot iron were not detected. Regnault (1847), who was the next to take up the subject as it happened with the same couple, made his condemnation sweeping enough. It was not the real perversity of the platinum iron couple which provoked Regnault, for of this neither he nor Pouillet became aware. Regnault's objection (as we should put it to-day) lay in the fact that the thermocouple obeyed Ohm's law, which in that early day lay somewhat beyond the great physicist's range of interest. Fortunately, but none the less long after, Becquerel followed with his palladium and divers platinum couples, carefully calibrated and efficiently used. What these platinum couples were is not stated. They cannot have been very sensitive or they would have been preferred to the palladium-platinum couple. Indeed, the metallurgy of platinum alloys did not reach a degree of refinement until Deville and Debray (1875) overhauled the chemical separation of platinum metals with particular reference, both to iridium and to rhodium. Recently Mylius and Förster at the Reichsanstalt further contributed to platinum metallurgy. But in view of the toils in which the whole subject of high temperature measurement languished in Becquerel's day, his results were not sufficient to remove the discredit

which Regnault had thrown upon thermo-electric pyrometry. And so it happened that the return to the method in recent date was of the nature of a resuscitation.

It is amusing to note, as we pass on, the pranks of custom as it bore down upon pyrometry. Following Deville and Troost, every worker (I might mention at least five) felt in duty bound to redetermine the boiling point of zinc—rather a difficult feat in its way. Thus we find boiling zinc inseparably associated with the destiny of the calibrated thermo-couple. Le Chatelier broke this law of fateful sequence by ignoring the need of calibration at the outset, and then using the couple so dignified to determine the melting points of silver, gold, palladium and platinum. But these are Violle's melting points. Hence the pyrometric feature of Le Chatelier's platinum-rhodium couple was in its inception due to Violle.

Meanwhile, accompanying the geologic inquiries of Clarence King, an extensive series of pyrometric investigations which had been in progress in this country since 1882 were completed (1887). These contained a full examination of divers efficient methods of pyrometry and a study of the porcelain air-thermometer with particular reference to the calibration of thermo-couples. In the course of this work the admirable pyrometric qualities of the platinum iridium alloy were exhibited by detailed and direct comparisons with the air thermometer. It was shown that the calibration could be made permanent by referring the thermo-electromotive forces to a Clark's cell; that the character of their variation with temperature is uniformly regular, and that the thermal sensitiveness of the couples increases as the higher degrees of red and white heat are approached. Finally, it was pointed out that couples destroyed by silicate corrosion or in similar ways could be restored by fusing over again on the lime hearth with merely negligible changes of constants. Elsewhere, Le Chatelier's clever combination of the platinum rhodium couple with the D'Arsonval galvanometer, then a comparatively new instrument in the laboratory, secured immediate favor. Professor Roberts-Austen, ever on the watch to waft good things across the channel from Gaul into Albion, hailed the new comer with no uncertain sound. Sometime after, the platinum-rhodium couple entered Germany and was there definitely calibrated (1892) for the first time, as already stated, at the Reichsanstalt.

Of the three available couples, palladium, platinum-rhodium and platinum-iridium, the former is excluded from competition by reason of its low fusibility. Between platinum-iridium and platinum-rhodium, the latter has been more extensively advertised, but is otherwise inferior to the older platinum-iridium alloy. In other words, platinum-iridium, when suitably alloyed, can be made more sensitive than platinum-rhodium in the ratio 100 to 76. Beyond this the alloys are much alike; both are tenacious, resilient, refractory metals, and their thermo-electric forces under like conditions of temperature show a constant ratio even at extreme white heats. The thermo-electric activity of these two alloys is exceedingly remarkable. Among over fifty different platinum alloys examined no similarly sensitive combinations were found. Moreover, whereas platinum alloys of extremely large electrical resistance are not unusual, such metals are not apt to be distinguished thermo-electrically.

To conclude: the small dimensions of the sensitive point of the thermo-couple, the independence of the intermediate temperatures between the junctions (apart from small corrections due to the Thomson effect) and therefore the removal of the terminal difficulty, the high upper limit of the measurable temperatures, the perma-

nence of its constants in relation to Clark's cell in the lapse of time, the instantaneity of its indications, the easy reproduction of destroyed couples, their relative insensitiveness to furnace gases, the regular and simple character of the temperature function, the sustained sensitiveness throughout all temperature ranges even quite into the fusion of platinum—all these facts are a sufficient if not overwhelming recommendation of the method.

In speaking of long range temperature variables one is hardly permitted to overlook the remarkable work which has recently been done in the direction of low temperature, but with these subjects I am less familiar and can therefore only refer to in passing. The progress made in the subject is sufficiently evidenced by the growth of large low temperature laboratories throughout the world, laboratories which undertake 'the cold storage' of 'cold storage,' as it were, like those of Pictet in Berlin and Paris, of Dewar in London, of Kamerlingh Onnes in Leyden, of Olezewski in Krakau, and others. Dewar and Fleming have added to our knowledge of the probable constitution of bodies at the absolute temperature. Olezewski has found the critical temperature of hydrogen at —230° and its atmospheric boiling point at —243°. Dewar and Moissan have liquefied fluorine. There is much here which I must reluctantly forego. The hydrogen thermometer, the platinum balance (Callendar) and the thermo-couple are again doing excellent work in thermometry.

APPLICATIONS OF PYROMETRY.

Turning now to the applications of recent pyrometry, we meet first many series of valuable data on melting points and similarly valuable data on the dissociation temperatures of chemical compounds. To these I merely refer, not being qualified to enter into chemical interpretations. High temperature boiling points have also been treated, and I will especially consider the case of the variation of metallic ebullition with pressure. The relation of vapor pressure to temperature has thus far defied the counsels of the wise, even though such men as Bertrand and Dupré have given the matter close scrutiny. One would suspect the simplest relation to hold for metallic boiling points, and investigations have therefore been undertaken in which the temperature of ebullition of Hg, Cd, Zn, Bi, were studied for pressures decreasing from one atmosphere down indefinitely.

The results so obtained show an effect of pressure regularly more marked as the normal boiling point is higher, so that the attempt to express the phenomenon for all these bodies by a common equation is roughly successful. By far the most rapid reduction of boiling point occurs when the pressure decreases from $\frac{1}{10}$ atmosphere indefinitely. For the case in which the normal boiling point is to be predicted from a low pressure value in case of a metal which, like bismuth, boils with great difficulty, very high exhaustion is essential.

Igneous fusion, by which I mean the fusion of rock-forming magmas, is particularly interesting in its relation to pressure. This has been again recently pointed out by Clarence King in his discussion of the age of the earth. If the earth is solid within, as is now generally admitted, such solidity can only result from superincumbent pressure withholding fusion. To study the relation of melting point to pressure directly is out of the question when white heat is the condition of fusion. In this respect the laboratory in the interior of the sun or even of the planets has some salient advantages, but we cannot comfortably put such a laboratory under strict surveillance of protoplasm.

Fortunately, the Clapeyron equation, successively improved by James Thomson and

by Clausius, is here usefully available. To measure the melting point, the difference of specific volumes of the solid and the liquid body and the latent heat of fusion at this temperature, with the aid of Joule's equivalent, is to measure also the relation of melting point to pressure implicitly. Based on the first and second laws of thermodynamics, this equation is generally true, no matter what specific properties may characterize the body. The process has thus far been completely pushed through for diabase only. Thermal change of volume may be measured by enclosing the rock in a platinum tube of known expansion, and the contraction of the contents from liquid to solid found by an electric micrometer probe reaching within the tube. Given a furnace fully under control, then, as experiment has shown, the cooling can be made to take place so slowly that platinum remains rigid relatively to its charge of red-hot magma, and under these conditions the contraction can actually be followed into the solid state. At the same time the temperature at which marked change of volume occurs is the melting point. Apart from difficulties of manipulation, the latent heat may be found from measurement of thermal capacity on either side of the temperature of fusion by a modification of known methods.

The rate at which fusion is retarded by pressure computed from these data in the manner specified showed an increase of the melting point of a silicate of about 0.025°C. per superincumbent atmosphere. But this datum falls within the margin (.02 . . . .04) of corresponding data much more easily and directly derived for organic bodies. One may, therefore, argue that if the melting point pressure rate is so nearly constant on passing from the class of silicious to the thoroughly different and much more compressible class of organic bodies the rate would probably be more nearly constant in the same body (silicious or organic), changed only as to temperature and pressure. This surmise was verified for naphthalene within an interval of 2,000 atmospheres.

The endeavor to interpret the change during fusion of the volume of the chemical elements in terms of the periodic system has been begun with much success by Max Töpler for low temperatures. It would be of great interest to complete this diagram for high temperatures in view of the specifically molecular character of the fusion phenomenon, by repeating such experiments as have just been described for rock magmas.

The heat conduction of rocks has been investigated in many cases for temperatures lying below red heat. Among recent observers we need only instance the extensive investigations of Ayrton and Perry. No trustworthy experiments, however, have yet been carried into the region of essentially high temperature; and yet what is chiefly of interest in the geological applications of such experiments is the change of conduction which accompanies changes of physical state, whether induced by pressure or by temperature.

Experiments in heat conduction are difficult under any circumstances. They become insuperably so when conduction at white heat is to be studied under pressure, and that is what the geological conditions actually imply. Some notion of a body respectively solid and liquid at a given temperature may be obtained by observing the behavior of bodies which are capable of being undercooled. A number of such bodies are known, thymol being a conspicuous example. Experiments with this body were made by measuring the volume expansion, specific heat and heat conduction in parallel series both for the solid and liquid state at like temperatures. They showed, for instance, that the increment of

absolute heat conduction, encountered in passing isothermally from the solid to the liquid state, when referred to solid conductivity is about 15%, and when referred to a liquid conductivity is about 15%. Similarly the change of thermometric conductivity under like conditions is an increment of 36% and 56% respectively. Now, since in most questions relating to thermal flow thermometric conduction enters exclusively, the importance of this large coefficient is obvious whenever a body passes from the solid to the liquid state.

Solid conduction is thus 40 or 50% in excess of liquid conductivity for the same body at the same temperature and pressure. It is reasonable to infer that a corresponding decrement of conduction will accompany any rise of temperature of a solid body. Measurements which have somewhat recently been made for relatively small intervals at Zurich, at Glasgow and at Harvard, upon typical rocks, all bear out this surmise. The immediate incentive to these experiments was a strong paper by Professor Perry in which Lord Kelvin's estimate of the age of the earth is shown to be insufficient for an earth in which the interior conductivity is systematically greater than the surface conductivity. Indeed, he deduces the percentage increment of the square root of the age of a Perry earth over that of a Kelvin earth to be one-fifth of the percentage decrement of conduction for each 100° C. So far as the effect of terrestrial temperature alone is concerned, the measurements just mentioned show that Perry's correction is negative or that Perry's earth would be less long-lived than the 100×10^6 limit of years set by Lord Kelvin.*

To estimate the effect on heat conduction of the increase of pressure which accompanies the increase of temperature with the depth below the surface is a much more serious matter. In the laboratory, pressure experiments are limited to 3,000 or 4,000 atmospheres; compared with earth pressures these scarcely amount to a scratch on the surface; yet even for this limit the determination of heat conduction at high temperatures is out of the question. A tentative method of arriving at a conclusion is given by Clarence King in his discussion of the age of the earth, the consequences of which have been quite overlooked. What King endeavored to accentuate long before Perry's contribution to the subject was precisely the fact we *cannot* assume greater conductivity for the interior than for the surface. Since heat conduction decreases isothermally from solid to liquid, it is assumed that in one and the same substance the viscosity could be taken as an index of the thermal conduction. Therefore, if temperature and pressure were made to vary in such a way (both increasing) as to leave viscosity constant, it was inferred that heat conduction would also remain constant. Now the isometrics or lines of constant viscosity of a viscous body for variable pressure and temperature are much more easily found than the isometrics of conduction. In fact, it has been shown that a burden of at least 200 atmospheres would have to be brought to bear in order to wipe out the decreased viscosity due to the rise of a single degree (Centigrade) of temperature. The depth at which this ratio is reached, as King points out, for a given surface gradient of temperature and depth, depends on the initial excess of the temperature of the earth considered, and on the age of the temperature distribution resulting. But no matter whether the Kelvin earth with an initial excess of 3,900° and an age of 100×10^6 years, or whether King's solid earth with an initial temperature of fused platinum and 25×10^6 years of life be taken, in all cases the temperature effect predominates

*The text of Kelvin's recent address at the Victoria Institute, in which an age of thirty million years is maintained, has not yet reached me.

throughout those depths within which change of temperature with depth is the marked feature of the temperature distribution. In other words, if, for example, we consider the Kelvin earth, the strata above .035 of earth radius will be strata of smaller conduction than the surface strata. From the surface downward as far as .035 radius, conduction will decrease to a minimum. Below this, conduction will increase again, due to preponderating pressure, finally to exceed the surface value. But the computed temperature distribution of Kelvin's earth is such that at .035 radius the initial temperature excess of 3,900° has been reached to within one or two per cent. Below this in depth Perry's correction will begin to apply, but the further changes of temperature are so nearly negligible that the consideration of conduction is superfluous. From this point of view, therefore, the staggering force of Perry's clever argument is removed. Of course, I am fully aware that an argument from the supposed parallelism of physical properties of a given body (in the present case heat conduction and viscosity) is not inevitably convincing; but in physical geology, for some time to come I dare say, the question will be not one of rigorous proof, but rather one of forming a rational opinion.

In passing I will indicate the importance of an increased knowledge of the isometrics of liquid and solid matter, relations which have thus far been found simpler in character than other thermo-dynamic properties, as I shall again point out in the course of the address.

I want finally to add a few words on the electro-chemistry of magmas. The physical chemistry of molten rock has already been somewhat extensively considered, but I am hardly competent to review it. In this country, Joseph Iddings and, more recently, George F. Becker have discussed the natural differentiation of magmas from different points of view. Here I will merely include certain pyrometric experiments on the electric conduction of fused glasses which seem to give promise of throwing light on the chemical constitution of complex silicates and to be suggestive in other ways. In such measurements, if the magma is made to pass from the solid to the liquid state, the observed electric conduction contains no evidence either of a melting point or of polymerism. The law of thermal variation is easily derived and it agrees closely with the corresponding behavior of a zinc sulphate solution, for instance, observed through a range of temperature. In a general way, electric resistance decreases in geometric progression when temperature increases in arithmetical progression. Considered relatively to the composition of the magmas, electric conduction shows a marked and regular increase with the degree of the acidity of the magmas. The less fusible acid magmas are better conductors than the basic magmas at the same temperature. Curiously enough, conduction thus runs in an opposite direction to fusibility. However viscous a magma may be, therefore, and however cogent the arguments, such as those launched by Becker against the differentiating importance of ordinary diffusion may prove, it is fair to conclude that a thorough change of chemical structure through *ionic* diffusion, whether directed by an electric field or otherwise, must be an easy possibility for a sufficiently hot but otherwise solid magma. The results point specifically to the desirability of repeating Hittorf's brilliant experiments on the migration of the ions for a silicious medium. This ought not to be difficult, seeing that such a menstrum need not even be liquid to be compatible with a high order of electric conduction.

Further consideration of the subject shows the probable passage of conduction through a maximum when acidity is con-

tinually increased. Finally quartz appears like an insulator in the same rôle as water in ordinary aqueous solutions. In all these cases I wish to keep in mind the results of Alexeëff and their recent repetition for metallic alloys, together with the interpretation of these results due to Masson. In a crust subject to variable magnetism, traversed by earth currents, sustained by semimetallic carbides of the Mendeleëff-Moissan type, containing piezo-electric and thermoelectric sources, who can say that electric fields are absent? Again, the character of the changes contemplated in Gibbs' famous 'phase rule,' as interpreted by Le Chatelier, would here be ionic rather than molecular.

A question of somewhat allied interest in the action of hot water under pressure on rock-forming silicates. Investigations of this kind have been described in the well-known and fascinating book of Daubrée. Daubrée's work, however, is qualitative in character, like that of many others in the same line, and the furtherance of the subject is to be looked for in the quantitative direction. Some time ago Becker suggested experiments on a huge mass of granulated rock under the action of steam at exceptionally constant temperature. But no thermal effect of the action of water could be detected. True, the boiling point of water is a temperature comparatively low for the purpose; yet similar experiments made with liquid water at over 200° under pressure were equally negative as to results. Experiments of this kind are not very conclusive. The insufficient sensitiveness of the measuring apparatus, the rate at which heat is carried off compared with the rate of generation and other obscure causes mar the results. The question may, however, be approached in a somewhat different way: If water is heated under pressure in glass tubes, the volume of water contained decreases as the square, whereas the chemically active area, *i. e.*, the inside surface of the tube, decreases as the first power of the diameter. Hence, in proportion as the tube is more capillary, the action of water on the glass will produce accentuated volume effects. Thus it was shown that the behavior of hot water is profoundly modified by its continued action on glass, inasmuch as its compressibility increases at a very rapid rate with the time of action even at 180°, until, with the approach of solidification, the observed compressibility is fully three times its isothermal value at the inception of the experiment. Even more striking is the simultaneous and continual decrease of the length of the column of water. Clearly, therefore, the confined volumes of glass and included water must undergo contraction at 180° in forming an eventually solid aqueous silicate, while increasing compressibility is due to the increasing quantity of silicate dissolved. Now, in nearly all cases the effect of solution is a decrease of compressibility. Hence the increased compressibility observed is to be referred to a precipitation of the dissolved silicate, in response to the action of pressure, a result borne out by the appearance of the tube and by varied correlative experiments. It is, however, the volume contraction which is particularly interesting, because of its far-reaching geological application. In the first place the measurements show that about .025 cubic cm. of liquid water is absorbed per square centimeter of glass surface at 180° C. per hour.* The effect of this absorption is a contraction of bulk amounting to 18% per hour. So large and rapid a contraction is presumably accompanied by the evolution of heat. Hence, under conditions given within the first five miles of the earth's crust, *i. e.*, if water at a temperature above 200° and under sufficient pressure to keep it liquid be so circumstanced that the heat produced

* This is an initial rate of about 180 kilograms per square meter per year.

cannot easily escape, the arrangement in question is virtually a furnace whose efficiency accelerates with rise of temperature or increase of terrestrial depth.

PIEZOMETRY.

It is not feasible to make much progress in pyrometry without feeling the need of a corresponding development in high pressure measurement. This has already appeared in the preceding parts of my address. It will not be expedient to look into the history of the subject as comprehensively as I did in the case of pyrometry, partly because the literature is more diffuse, and partly because the real development of piezometry is of recent date and virtually begins with pressures of the order of several thousand atmospheres. So understood, although we gladly pay homage to Oersted, to Regnault, to Grassi and many others, our historical summary may be abridged.

As is often the case in physics, the great advances in the subject are associated with the name of one man; for, though many able investigators have contributed effectively to the progress of piezometry, the overshadowing importance of the results of Amagat have superseded all researches coextensive with his own. For over twenty years Amagat has been laboring on this definitely circumscribed subject. Year after year his prolific experimental ingenuity has put forth results, each of which in its turn constituted the highest attainment in accuracy and the greatest breadth of scope which high pressure measurement had reached at the time. It is impossible to give any adequate view of this sustained labor in an address. The subject is highly specialized and demands special treatment; but we owe to Amagat the bulk of our knowledge of the properties of a gas regarded not as an ideal fluid, but as a physical body; some of the most far-reaching results in the thermo-dynamics of liquids, and some of the best data in the elastics of solids.

Amagat investigated gases within an interval of pressure which at times reached 4,000 atmospheres, with a view to interpreting their divergence from the laws of ideal gaseity. Indeed, we may note in passing that just as the advanced astronomy of the day is being enriched with unexpected discoveries from a discussion of mere errors of observation, so refined physical measurement gleans new harvests in carefully tracing out the all but rigorous sufficiency of established laws. The product of pressure and volume, nearly constant in the ordinary isothermal behavior of gas, shows, under higher pressures, a well-marked passage through a minimum in the case of all gases except hydrogen. Hence, below a certain definite pressure, varying with the character of the body (say 40 atm.), gases are more compressible than Boyle's law asserts, and above this pressure they are continually less compressible and begin to resemble hydrogen in this respect. The sharpness of the minimum diminishes as temperature increases, and probably ultimately vanishes. Cailletet, it is true, had undertaken a study of the same subject simultaneously, but his results were not in the same degree correct. Again, the coefficient of expansion of gases, considered in its isopiestic behavior for temperatures not too far above the critical point, increases with pressure to a maximum, which seems to occur at the same pressure for which the volume-pressure product is a minimum. This thermal maximum also decreases with temperature and finally vanishes. To specify the conditions further than this would be to exceed the limits beyond which verbal statement ceases to be lucid. The value of Amagat's work, however, is not merely the formulation of such general laws for gases as a whole, but rather the investigation of sharp and specific results for each gas individually. Thus,

if one uses these data for a given gas to compute the contestants in Van der Waal's law, one is actually able to predict remote critical conditions of the gas in question with a fair order of accuracy.

Whenever pressure measurements are to be made through such large intervals as are here in question, the elastic constants of the apparatus become of increasing moment. Amagat, however, treated these incidental measurements as of like importance with the rest of his labors. The starting point of his investigation into high pressures was the open mercury manometer first erected along a staircase near Lyons, finally in the shaft of the St. Etienne mine, about 380 meters deep. This apparatus was used for graduating the closed manometer, preferably containing nitrogen. In later experiments for excessively high pressures the closed manometer was replaced by the 'manomètre à pistons libres,' a sort of inverted Bramah press, in which the small pressures of an open mercury manometer acting on a large piston compensate the relatively large pressures of the piezometer acting on a small piston. The ingenious feature of Amagat's apparatus is the rotation of both pistons just before measurement, a device by which friction is rendered harmless. Equipped with this instrument direct determination of the bulk modulus for glass and metal was actually feasible. In the case of glass no serious variation of the compressibility could be ascertained within 2,000 atmospheres, and even 200°, an observation of great value in practical research. Poisson's ratio was similarly determined and the data used in computing Young's modulus. But the most important result of these researches, a result to which Professor Tait also contributed, is the datum found for the absolute compressibility of mercury. This will enable all future observers in piezometry to standardize the apparatus with ease and nicety.

Time prevents me from dwelling upon the remaining investigations of Amagat in a measure commensurate with their value. These contain a counterpart for the liquid state of the results already announced for gases. The change of volume throughout enormous pressures and about 200° of temperature is considered in detail for a number of important liquids. Only in one case, and that the rather remarkable one of carbon tetrachloride, are evidences of solidification encountered and the conditions determined. Amagat believes the absence of solidification to be due to the occurrence of the lower critical temperature below the isothermal of compression. In my own judgment, however, the pressures necessary to reach this lower critical point will be enormous even in units of 1,000 atmospheres, for which reason it is not in any case liable to be an easy conquest.

Special mention finally is due to the thermal position of the maximum density of water, which Tait had already studied. Amagat shows definitely that the temperature of maximum density moves towards the freezing point with increasing pressure, so that at high pressures, as well as at high temperatures, the behavior of water loses its anomalous character. In general, compressibility and expansion decrease with pressure for all normal liquids, and expansion increases rapidly with temperature. Other anomalous properties of water have been investigated, among which the diminished viscosity of water under pressure at ordinary temperature studied by Röntgen, Cohen and others may be stated.

After this cursory and wholly inadequate mention of the work of Amagat and the physicists who, like Tait, Cailletet and others, have been engaged in closely allied researches, it will repay us to look at some of the other as yet less splendidly developed contributions to piezometry. At the outset it is well to make mention of the forms of

pressure gauges which have come into use. As far as 1,000 atmospheres, the Bourdon gauge, if well constructed, does good service, though in a somewhat rough way. The corrected nitrogen closed manometer is more accurate for a smaller range. A theoretically simpler pressure gauge was proposed by Tait and Cailletet. In this case a straight cylindrical elastic tube under internal or external pressure is substituted for the Bourdon tube and the expansion or compression is directly measured. With due precautions against changes of temperature and the choice of a solid of constant bulk modulus and rigidity, this gauge can be used as far as about 2,000 atmospheres with convenience.

Above 2,000 atmospheres Amagat's Bramah press manometer, already mentioned, is the only reliable gauge, and, though somewhat cumbersome, has the advantage of giving absolute results. However, a gauge based on the change of electric resistance of mercury with pressure, a constant now fairly well known from Palmer's measurements, will, in my judgment, do good service for pressures which exceed even the range of the manometer. With regard to methods for producing high pressures, the force pump, with a small steel plunger and the screw advancing bodily into a closed barrel filled with a liquid, have not yet been superseded. The efficiency of such apparatus depends essentially on the means used for obviating leakage. These must, of course, be very perfect.

Amagat's work with liquids was extended chiefly in the direction of high pressures Experiments have since been made by others throughout higher temperatures (310°) and, of course, a smaller range of pressures (500 atm.). Leaving out the less perspicuous results, I will here merely allude to the probable existence of a remarkable law which these researches have developed. Dupré (1869) and afterwards Lévy (1878), reasoning from thermo-dynamic premises, were the first to suspect that the isometrics or lines of equal volume of liquids are straight. In other words, if there is to be no change of volume then pressure increments must vary proportionately to the temperature increments ($p=a\,\theta-b$), a result which implies that the internal pressure of a body kept at constant volume is proportional to its temperature. Lévy's deduction was, however, declared to be theoretically unwarrantable by Clausius, Boltzmann and others. Sometime after, the same law reappeared in experimental form in a series of brilliant researches on critical temperatures due to Ramsay and Young. Fitzgerald, reasoning from Ramsay and Young's results, then proved that for such liquids as possessed straight isometrics specific heat is a temperature function only, and energy and entropy are each expressible as the sum of a mere temperature function and a mere volume function. This is curiously like the position from which Dupré and Lévy started. Ramsay and Young's work, however, applied specifically to vapors, and for high temperatures (200°) their pressures did not exceed 60 atmospheres. The law has since been tested for liquids as far as 1500 atmospheres and over 200° conjointly, and found in reasonable accordance with experiment. Hence we infer that if the thermo-dynamic change of a body is such that volume remains constant, pressure and temperature will vary linearly with each other, the increments being about 0.1° C. per atmosphere. Now, although any law relating to the liquid state would be welcome, these volume isometrics are particularly so. In the geology of the earth's crust, for instance, they would, in a great measure, determine the conditions of possible convection; and it is curious to note that, from the known values of bulk modulus and of the expansion of solid glass, the isometrics

would here again be given by corresponding increments of about .1° per atmosphere. For solid metals the isometrics are of a different order.

Another line of research for liquids to which I attach supreme importance has only just been begun: I refer to the systematic study of the *entropy* of liquids. Among the first results on the heat produced in suddenly compressing a liquid are those of Tait. They are of too limited a range, however, and not in good accord with the more recent and extended data of Galopin. Generally speaking, the change of temperature produced per atmosphere of compression increases with temperature in a marked degree, as one may infer from Kelvin's equation. For organic bodies this increment at ordinary temperatures is of the order of $\frac{1}{50}° = .020°$ per atmosphere. In case of liquid metals the order of values is decidedly different, being about $\frac{1}{10}$ this value, recalling correspondingly divergent results observed for the isometrics of volume. Quite recently (1896), the same subject has been taken up by Tammann (to whom we also owe results for the correlative compressibility) particularly for solutions and with reference to the theory of solutions. Tammann's data are of the order .001° per atmosphere at 0°, and in better keeping with the thermo-dynamics of the subject than the earlier experiments. Much more, however, must be done before anything like a degree of critical accuracy is approached or a broad survey taken. Pressure intervals are to be chosen wider and the temperature measurement given with greater certainty.

Finally, I wish to touch upon the relations of melting point and pressure in their more recent development. Obviously, the classical work of Andrews on the continuous passage of a liquid into the gaseous state will find some counterpart in the manner in which the analogous passage from the solid into the liquid state takes place. The character of these phenomena may be shown from direct observations of melting point and pressure, as was done by the earlier observers. Full knowledge, however, can be obtained only by mapping out the isothermals throughout the region of fusion very similarly to the method pursued by Andrews himself for vaporization. This has thus far been attempted for a single body only, naphthalene, within 130° and 2,000 atmospheres. Six isotherms (63°, 83°, 90°, 100°, 117°, 130°) were traced within these intervals, along each of which, excepting the first, the body passed from the liquid to the solid state under the influence of pressure only. An exhibit of these data shows strikingly that in all cases the change of physical state takes place in accordance with a cyclic law, *i. e.*, a larger pressure is necessary to change the body from the liquid to the solid state, at a given temperature, than the pressure at which the body at the same temperature again spontaneously melts. Freezing almost always seems to take place at once; the corresponding fusion is apt to be prolonged, and in its gradual occurrence traces the contours of James Thomson's well-known, doubly-inflected isothermals much more fully than does the allied case of vaporization.

The appearance of the cyclic parts of these isothermals is suggestive, and may be described in terms of their dimensions in the direction of volume and of pressure respectively. The former dimensions indicate the probable fate of the volume increment. They show that, as pressure and temperature increase, the volume increment tends more and more fully to vanish, and they thus imply a lower critical temperature at which the solid would change into the liquid continuously as far as volume is concerned. It does not follow that other properties of the body would here also vary

continuously. For naphthalene this point would lie in a region of several thousand atmospheres and several hundred degrees Centigrade—therefore, in a region too remote to admit of actual approach.

Again, the breadth of the cycles, measured along the pressure axis, decreases from the center of the field both in the direction of increasing and decreasing pressures. The tenor of these results is an additional indication of the recurrence of a lower critical temperature at which cycles must necessarily vanish. The decrease of the breadth of the cycles in the direction of decreasing pressure suggest the possible occurrence of a point in the region of negative external pressure, so circumstanced that beyond it the substance would solidify at a lower pressure than that at which it fuses. This may be interpreted as follows: The normal type of fusion changes continuously into the ice-type of fusion through a transitional type characterized by the absence of volume lag.

An independent discussion more searching in character has quite recently been given by Tammann. Tammann points out that for the normal case of fusion and for increasing pressure the two determinative factors of the Clapeyron equation—the volumes and latent heat of fusion—will not in general simultaneously become and remain zero. He argues that the volume constant will at the outset decrease with pressure passing through zero to negative values. Hence the curve representing the relation of melting point to pressure must initially rise to a maximum when the melting point pressure ratio is zero, and then decrease. Contemporaneously, the latent heat of fusion, decreasing continually with pressure, eventually also reaches zero, but at a much later stage than the volume constant. At this stage, therefore, since the melting point and the volume constant now have definite values (the latter negative), the melting point and pressure ratio is negatively infinite. Hence the curve expressing the relation of melting point to pressure decreases with increasing pressure from the maximum specified, as far as the pressure at which latent heat is zero, and there drops vertically downward. Thus Tammann's melting point pressure curve, with its initial and final ordinate in the direction of temperature, maps out a field of pressure and temperature within which the body is solid. Outside of this region the body is liquid and cannot by pressure alone be conceivably converted into the solid state. Any thermo-dynamic change involving a march through the boundary of this region is accompanied by the discontinuity of fusion, of viscosity, etc. A march through the final ordinate (for which latent heat is zero) is probably not accompanied by such discontinuity. For a given temperature there may be two fusion pressures. At a temperature sufficiently below the melting point the continued increase of pressure should, therefore, move the normally fusing body from the solid into the liquid state continuously. This is a somewhat anomalous result of close reasoning, but it must not be forgotten that in the depth of our ignorance of the actual occurrences above several thousand atmospheres the term anomaly is a misnomer. Indeed, if we regard the melting pressure curve beyond the stated maximum as characterizing the ice type of fusion (which Tammann does not do) our difficulties would in a measure be reconciled.

Tammann finally points out that the term lower critical temperature is not justified by the character of the phenomenon. Data for melting point and pressure due to Damien seem directly to corroborate the occurrence of zero values in the ratio of melting point and pressure increments, but Damien's tests are restricted to a pressure interval much too small to be trustworthy.

Of the two bodies which have been tested throughout long pressure intervals, naphthalene shows a linear melting point and pressure ratio for 2,000 atmospheres, while the carbon tetrachloride of Amagat, though initially concave upward, soon also becomes linear. Clarence King has, therefore, in geological considerations so represented it. To conform with Tammann's inferences the interior of the earth would have to be a fluid.

One point of issue, however, in these cases is clear: At Andrews' critical temperature both the difference of specific volumes and the latent heat of fusion vanish simultaneously wherever observed. Under corresponding conditions of change from liquid to solid the internal pressures are of tremendously greater value for both states, and the passage of the solid into the liquid molecule may involve an immense transfer of energy without any corresponding change of volume, for the density of the molecule itself eludes observation. The manner of this isothermal change from one state to the next is in all cases along the characteristic doubly-inflected contour first pointed out by Thomson for vapors, and since elaborated by Van der Waals, Clausius and others. We may, for brevity, call this a *volume lag* and measure it in terms of the pressure or the volume interval subtended. The liquid can exist even above the critical temperature, which would mean that even here pressure must be reduced below the critical pressure in order to rupture the liquid molecule.

Pronounced as these phenomena are for the change from gas to liquid, they become much more remarkable, indeed often formidable, for the change from liquid to solid. In this case a volume lag subtending more than 100 atmospheres is the rule. In other words, it takes much greater pressure to solidify a liquid at a given temperature than to liquefy the solid. Among all these cases there is a group of well-known bodies in which, while the solidification pressure is of marked intensity, the isothermal pressure of spontaneous fusion may even be below zero or be in the region of negative pressure. Take the single example of thymol among many: This body between zero Centigrade and its melting point at 53° can be kept in either the solid or the liquid state of pleasure. Given at about 50° in the liquid state it would require more than 2,000 atmospheres to solidify it. If solid it must obviously remain so even if pressure be wholly removed. But thymol may be similarly treated beginning with the undercooled liquid state at 28°, *i. e.*, 25° below its melting point. Even here at least one thousand atmospheres are needed to condense it (400 have been tried quite ineffectively). Once solid it would require about 1,000 atmospheres of *negative* external pressure again to melt it. In other words, it could not be melted again on the same isothermal.

If we but knew more about the physical constants involved in these transformations we could predict the results along the lines of J. W. Gibbs' splendid theory of the equilibrium of heterogeneous mixtures; but, with the dearth of our concrete knowledge of long range physical phenomena relating to liquids and solids, we must be content with humbler methods.

I have always regarded the significant behavior instanced for the case of thymol as capable of a broad interpretation. Professors J. J. Thomson and Fitzgerald abroad, and Elihu Thomson in this country, have recently sought for atomic dissociation in the electrolyzed vacuum of a Crookes' tube. Speaking to the same point, I would venture to assert that we may reasonably look to the volume lag for a rational account of the genesis of atoms. We have already met with two orders of volume lag: the first at the mergence of gas into liquid being usually a few atmospheres in isothermal

value; the second at the mergence of liquid into solid, a hundred or even one thousand times as large in isothermal value, and characterized by the fact that, whereas freezing pressures may be enormous, the corresponding isothermal melting pressure may even be markedly negative.

If, then, we further inquire as to what will happen if we indefinitely compress the solid along a suitable isothermal, I think it is logically presumable that, with the succeeding and profoundly accentuated volume lag, we shall reach the next atom in a scale of increasing atomic weights.

However enormous the condensation pressure for this purpose may be, it is supposable, in the light of the examples already given, that along an accessible isothermal the disintegrating external pressure of the new atom may be permanently negative. Hence the new atom will persist within the pressure and temperature range available in the laboratory.

But the last stage is virtually identical with the first, or the inherent nature of these changes is periodic. The inference is therefore that, under suitable thermal conditions and continually increasing pressure, the evolution of atoms, of molecules, of changes of physical state, again of atoms and so on indefinitely, are successive stages of periodically recurring volume lag.

CARL BARUS.

BROWN UNIVERSITY.

THE AMERICAN MATHEMATICAL SOCIETY.

THE American Mathematical Society held its fourth annual meeting at Toronto, Canada, on Monday and Tuesday, August 16th and 17th. All conditions were exceptionally favorable for the success of the meeting, but the result far exceeded all anticipations. Forty-four members of the Society were registered as in attendance, forming by far the largest body of mathematicians ever brought together on this continent. Among those present were Professor Simon Newcomb, President of the Society, and former Presidents Dr. G. W. Hill and Dr. Emory McClintock. Several distinguished visitors also attended the meeting, among them Professors A. R. Forsyth, A. G. Greenhill and O. Henrici. Twenty-three papers were presented, all by members of the Society. Although the great length of the program necessitated a severe limitation of time for the reading of each paper, the hearty cooperation of the authors with the plans of the committee enabled the Society to conclude the sessions in the two days allowed without the least friction. The meeting was characterized not only by great scientific interest, but also by a cordial spirit of good feeling between hosts and guests.

At the meeting of the Council on Monday evening three persons were elected to membership in the Society and three nominations were received. It was decided to hold the next summer meeting of the Society at Boston, Mass., at or about the time of the meeting of the American Association for the Advancement of Science. Resolutions were adopted by the Society in recognition of the generous hospitality of the University of Toronto and its officers.

A portion of the afternoon session on Tuesday was devoted to a general discussion of the topics mentioned below. The members of the Society were afterward received by President and Mrs. Loudon, of the University of Toronto. On Tuesday evening the members of the Council were entertained at the Toronto Club by Professor Alfred Baker.

The following is a complete list of the papers presented:

MONDAY MORNING.

1. *Upon the representation by ruled surfaces of the curves drawn by mechanisms. Preliminary report, illustrated by models:* DR. EDWIN M. BLAKE, Purdue University.

2. *A contribution to the theory of plane curves:* DR. L. WAYLAND DOWLING, University of Wisconsin.

3. *A Canadian discoverer of the non-Euclidean Geometry:* PROFESSOR GEORGE BRUCE HALSTED, University of Texas.

4. *Note on the Folium of Descartes:* PROFESSOR ELLEN HAYES, Wellesley College.

5. *A geometrical locus connected with a system of coaxal circles:* PROFESSOR THOS. F. HOLGATE, Northwestern University.

6. *On the solution of the map-color problem:* PROFESSOR P. WERNICKE, State College of Kentucky.

7. *On the Riemann-Helmholz-Lie problem of the foundations of geometry:* PROFESSOR H. B. NEWSON, University of Kansas.

MONDAY AFTERNOON.

8. *Quaternion invariantive operators:* PROFESSOR JAMES BYRNIE SHAW, Illinois College.

9. *The geometry of some differential expressions in hexaspherical coordinates:* DR. VIRGIL SNYDER, Cornell University.

10. *On certain differential equations of the second order allied to Hermite's equation:* PROFESSOR E. B. VAN VLECK, Wesleyan University.

11. *Concerning the cubic involution and the cubic transformation of elliptic functions:* PROFESSOR OSKAR BOLZA, University of Chicago.

12. *The determination of the rational function in the reduction of the general Abelian integral to the sum of a rational function and a fundamental system of elementary integrals:* DR. J. C. FIELDS, Berlin, Germany.

13. *On the reduction of hyperelliptic functions ($p=2$) to elliptic functions by a transformation of the second degree:* D. J. I. HUTCHINSON, Cornell University.

TUESDAY MORNING.

14. *Further researches in the theory of quintic equations:* DR. EMORY MCCLINTOCK, New York, N. Y.

15. *A theorem concerning the coefficients of lineal substituting groups of finite order with n variables:* PROFESSOR H. MASCHKE, Chicago University.

16. *On the commutator groups:* DR. G. A. MILLER, Ann Arbor, Mich.

17. *Collineations in a plane with invariant conic or cubic curves:* PROFESSOR H. S. WHITE, Northwestern University.

TUESDAY AFTERNOON.

18. *Concerning regular triple systems:* PROFESSOR E. H. MOORE, University of Chicago.

19. *Theory of discrete manifolds:* MR. F. W. FRANKLAND, New York, N. Y.

20. *Certain transformation problems of canonical equations of dynamics:* DR. EDGAR ODELL LOVETT, University of Chicago.

21. *The true transition curve:* MR. P. H. PHILBRICK, Lake Charles, La.

22. *About sixth power numbers whose sum is a sixth power:* DR. ARTEMAS MARTIN, Washington, D. C.

23. *Preliminary report on alternate functions of complex numbers:* PROFESSOR A. S. HATHAWAY, Rose Polytechnic Institute.

General discussion of the following topics:

1. *The accurate definition of the subject-matter of modern mathematics.*

2. *The vocabulary of mathematics. The possibility of correcting and enriching it by cooperative action.*

F. N. COLE,
Secretary.

CURRENT NOTES ON PHYSIOGRAPHY.

ARTESIAN WELLS OF IOWA.

A COMPREHENSIVE report on the artesian wells of Iowa by W. H. Norton (Iowa Geol. Surv., VI., 1896, 113–428) brings clearly forward the favorable conditions there obtaining for this important source of water supply. The paleozoic strata have a gentle southward inclination, and also a sag over the northern part of the State from the eastern and western boundaries towards a median line. Numerous water-bearing strata, or *aquifers*, occur, from the basal sandstone that lies on the buried hills and valleys of the Algonkian floor to the sandstones of the coal measures. Cretaceous strata in the northwestern part of the State lead water away westward. Some important wells are supplied from aquifers in the glacial drift. Three artesian wells were mentioned in the State Survey Report for 1870, and no systems of water works had been then constructed. About a hundred systems are now in operation, many of them depending on artesian supply. At certain points, where many wells have been sunk, the first yield has slightly decreased, as if the limit of local supply had been reached; but great stores of subterranean water remain unexhausted beneath most of the State.

FORESTS AND DESERTS OF ARIZONA.

THE variation of climate with altitude

and the redemption of the desert along irrigated valleys afford material for an entertaining narrative by Fernow (Nat. Geogr. Mag., VIII., 1897, 203–226). Much of the lower ground is desolate, unless exceptional rains allow a temporary growth; but the few valleys of streams large enough to feed irrigating canals contain green groves, orchards and fields. The higher plateaus and volcanoes bear forests of open growth; about Flagstaff 12,000,000 feet of lumber are cut annually. The open grouping of the trees is ascribed to variation in water storage by the soil. Although millions of pine seedlings spring up after the rains, all of them perish from frost, unless the season is exceptionally favorable. The young tree growth does not follow in annual generations, but in irregular periods of from three to ten years. Open grassy glades of fine black loam seem to mark the site of extinguished lakes. Brief account is given of an ascent of San Francisco mountain and of a visit to the Grand Canyon of the Colorado, but it seems rather negligent of the rest of the world to speak of even the unrivalled canyon as 'a thought of God on earth expressed.'

TRANSVERSE VALLEYS IN THE JURA.

A NEW contribution to the above much-discussed question is made by Dr. Fr. Jenny, (Das Birsthal: ein Beitrag zur Kenntniss der Thalbildung in Faltengebirge, Basel, 1897), with the conclusion that the several transverse valleys or *cluses* of the Birse are the result of backward erosion along lines of local distortion in the anticlinal ridges, whereby the river course has become more or less adjusted to the structure of the region. It is argued that in the early stages of folding, the drainage was consequent, and that several temporary lakes were then formed. Local deformation in the growing arches defined the river course. "The Birse has gained its present course by a change from its original path through adjustment to the structure of the mountains that it traverses."

It is not clear whether the author advocates the diversion of early consequent streams to transverse courses by the headwater growth of diverting streams or not; no explicit statement being made on this point. The antecedent origin of the rivers, advocated by Foerste and Rollier, is discarded. Yet a qualified antecedent origin is implied, for the present river course is given an early date, before the folding was nearly completed; as if consequent on the early folding and antecedent to the rest. The value of adjustment to internal structures in locating the river seems exaggerated. Even if essentially antecedent, the slight adjustments now found within the cluses might have taken place as the valleys were deepened. Moreover, it is highly probable that slight irregularities of structure, such as those to which Jenny ascribes the location of the existing cluses, would have been found wherever the cluses had been cut down across the anticlines. The frequent occurrence of cluses near the end of pitching anticlines is quite as suggestive of a course consequent upon initial folding and antecedent to later and greater folding as of dependence on slight local deformations.

SUB-OCEANIC CHANGES.

MILNE draws attention to sub-oceanic changes (London Geogr. Journ., X., 1897, 129–146) caused by slides of detritus down the marginal slopes of continental plateaus. Cables are there broken in consequence of their burial beneath such slides. The cause of the movement is ascribed to the accumulation of land-worn detritus. In Japan a large number of earthquakes come from the deep sea off the mouth of the Tonegawa, the largest of Japanese rivers, which crosses an alluvial plain in its lower course. Many other shocks on those islands have similar

origin. Where long continental slopes descend beneath the ocean at a steeper gradient than 1 in 35, slips and earthquakes of this kind may be expected. The western boundary of the Tuscarora deep, in the North Pacific, is a source of many earthquakes, among them the destructive disturbance of June 15, 1896. There Milne infers 'sudden sub-oceanic changes along the basal frontier of a continent, the magnitude of which it is difficult to estimate.' Certain 'unfelt earthquakes' recognized by the horizontal pendulum are recorded at widely separated stations, 'and it is fair to assume that in these instances the whole world has been shaken.' Their source cannot have been on any land, for then they must have been observed in the ordinary manner; they are therefore ascribed to submarine movements.

If the occurrence of sub-oceanic slides be verified, they afford a new argument for the permanence of continents and oceans; for nowhere do the sedimentary strata of the continents exhibit so confused a structure as must be thus produced along the slope and basal frontier of a continental mass.

W. M. DAVIS.

HARVARD UNIVERSITY.

CURRENT NOTES ON ANTHROPOLOGY.

STONE IMPLEMENTS FROM THE POTOMAC DISTRICT.

PROFESSOR WILLIAM H. HOLMES contributes to the Fifteenth Annual Report of the Bureau of Ethnology one of his excellent and beautiful papers, this one on the 'Stone Implements of the Potomac Chesapeake Tidewater Province,' 152 pages, with 104 full-page plates, and 36 figures in the text. The geographical and geological relations of the area are carefully explained, and the artefacts themselves are examined under the classification of flaked, battered or abraded, and incised or cut stone implements and utensils. The typical forms and characters are illustrated, the processes of manufacture are set forth, and the extensive quarries where the material was obtained are described.

The conclusion of the author, after years of patient research with reference to the antiquity of man's work in this region, may be given in his own words (p. 146): "The art remains preserved to our time indicate the prevalence of extremely simple conditions of life throughout the past, and exhibit no features at variance with those characterizing the historic occupancy." So that we shall have to go elsewhere to find 'paleolithic man.'

ETHNOGRAPHY OF THE CALCHAQUIS.

IN SCIENCE, May 7th, I referred to some interesting art remains discovered by Ambrosetti in the territory of the ancient Calchaquis. Ethnographers have been unable to identify these with any modern tribe (see 'The American Race,' p. 319). The latest effort is by Dr. Ten Kate. He availed himself of a series of skeletons in the Museo de La Plata, exhumed from old graves in Calchaqui territory. Some were deformed, and of the normal there were a number of types; but the characteristic features were extreme brachycephaly and a short stature. In both respects these ancient differed from the modern natives of the place. Looking around for similarities, Dr. Ten Kate found them among the Huarpes of the province of La Rioja, where skeletons with the same traits occur. He does not, however, identify them with the Huarpes (or Allentiacs), who are probably related to the Chaco tribes, but rather with the Araucanian stock, so far as one can judge from the synopsis of his conclusions in the *Centralblatt für Anthropologie.*

These analogies are not borne out by the linguistic evidence of the proper names in

Calchaqui territory, which rather points to Aymara or Kechua affinities as undoubtedly to the arts of this extinct population.

D. G. BRINTON.

UNIVERSITY OF PENNSYLVANIA.

NOTES ON INORGANIC CHEMISTRY.

MODERN ALCHEMY.

DR. H. CARRINGTON BOLTON contributes to the last *Chemical News* an article entitled 'Recent Progress of Alchemy in America.' It is largely devoted to such details as are known of the claims of Dr. Stephen H. Emmens, of New York, and of Edward C. Brice, of Chicago, together with the Mint Report on the Brice process. Dr. Emmens is the inventor of the high explosive Emmensite, and the author of the 'Argentaurum Papers.' It is perhaps worth while to give a brief abstract of his claims, taken from his own publications. He states that he was led to his present study by the investigation in 1892, at the instance of Commodore Folger, of a specimen of rustless nickel steel, which it was proposed to use for torpedo netting. He says that he found in both nickel and iron, and subsequently in cobalt, 'a certain product which seemed to differ from anything recorded in the text books.' Inferring that, if such a substance were found common to the metals of the fourth series of Mendeléeff's group eight, similar results would be found in other groups, he began the study of gold and silver. 'By certain physical methods and by the aid of certain apparatus' he claims to have succeeded in bringing about an extremely minute subdivision of silver, and was 'surprised to find that the substance obtained differed so far from ordinary silver that it could no longer be regarded as the same elementary substance.' His alleged substance, which he calls *argentaurum*, symbol *Ar*, he considers to be the missing element between silver and gold in the second subdivision of Mendéeleft's group two. "Argentaurum can be aggregated into molecules having a density considerably superior to that of silver molecules, and, we think, identical with that of ordinary gold molecules. Whether we are right as to this or not, the condensed argentaurum presents the appearance and is endowed with the properties of ordinary metallic gold." Dr. Emmens estimates that 'one ounce of silver will produce three quarters of an ounce of gold' at a profit of at least three dollars an ounce. He operates on Mexican dollars, and has sold to the U. S. assay office six ingots of an alloy of silver and gold aggregating in value $954.80. Dr. Emmens remarks: "The gold-producing work in our argentaurum laboratory is a case of sheer mammon seeking; it is not being carried on for the sake of science, or in a proselytizing spirit; no disciples are desired and no believers are asked for. I have every confidence that the production of argentaurum gold will be brought up to 50,000 ounces monthly within a year." Should this result be attained, the problem of bimetallism will be happily solved.

REGARDING the Brice process, three government experts worked for three weeks under Mr. Brice's direction, and officially report: "We have seen not the slightest evidence of any 'creation' or transmutation. On the contrary, the claimant failed in every instance to recover the entire amount of silver and gold known to be present in the materials. The claimant seems to have devised a variety of irrational and wasteful methods for recovering a portion of the silver and gold known to metallurgists as being present in many commercial metals, such as antimony and lead." Mr. Brice's application for a patent has been again rejected. Incidentally, the assay office investigation revealed that commercial antimony contains a very small percentage of gold, which is recovered by the Brice process.

APROPOS of argentaurum, Dr. Emmens and Newton W. Emmens publish in the *Chemical News* a short article on 'Migrant Matter,' describing an experiment in which a disc of pure lead connected with a disc of pure silver by a copper spiral was kept in a wide-mouthed bottle for twelve weeks. At the end of this period the lead disc on cupellation is said to have given a silver bead weighing 0.00003 gram. "It would appear from this experiment that what is commonly recognized as solid silver is, in part at least, a migrant mode of matter * * *. We use the term 'migrant matter' because the traveling particles to which we refer are (in common with odors generally) much more akin to Crookes's 'fourth form' than to gases."

J. L. H.

SCIENTIFIC NOTES AND NEWS.

THE INTERNATIONAL MEDICAL CONGRESS.

THE New York *Medical Record*, with great enterprise, secured by cable a report, extending to a number of pages, of the Twelfth International Medical Congress, which opened at Moscow on August 19th. After the Congress had been opened by the Grand Duke Sergius and welcomed by the Minister of Public Instruction, Hospodin Dylianov, Professor Sklifosovsky, the President of the Committee of Organization, made an address in which he dwelt especially on the relations of Russia to the rest of Europe in regard to medical and scientific work. He said that one great obstacle to medical progress was the want of a common medium of communication between the men of science of different nationalities. Nowhere was this almost fatal lack so fully realized as in Russia. The great mass of Russian medical literature was a sealed book to Western peoples, and few outside of the country had any conception of the enormous amount of scientific work that was being done there. Russians recognized that their language was too difficult ever to become universally known, and they were therefore the more keenly alive to the necessity of the adoption of some international speech. He would suggest the appointment of a committee to draft a preliminary agreement on the subject, which should be laid before the next congress for consideration. The General Secretary, Professor Roth, reported an attendance of 7,300 members in Moscow. Of this number more than 3,500 were from Russia, 800 from Germany, as many from Austria, 400 from France, 300 from Italy, 300 from England, 120 from the United States, 30 from Mexico, 10 from Japan and 4 from China. Prince Gallitzin, the Mayor of Moscow, then greeted the members of the Congress on behalf of the municipality and announced that the city of Moscow had decided to establish a prize of 5,000 francs, to be awarded at each international congress, to the person who in the interval since the preceding congress shall have done that medical work which shall be deemed of the greatest benefit to humanity. Addresses were then made by the national delegates, and the honorary presidents were announced as follows: Germany—Virchow, Leyden, Ziemssen and Waldeyer; Austria — Gussenbauer, Hlawa and Rudiger; Great Britain—Stokes, MacCormac and Simpson; United States—Senn and Thayer (Billings, it was announced, would have been one of this number had he not been absent); Spain—Robert; France—Lannelongue, Le Dentu, Grasset and Pinard; Italy—D'Antona, Bottini and Lombroso.

General addresses were given by Professor Virchow on the continuity of life; by Professor Lannelongue on the sclerogenic treatment of surgical tuberculosis; by Dr. T. Lauder Brunton on the relationship of physiology, pharmacology, pathology and practical medicine; by Professor von Krafft-Ebing on etiology of progressive general paralysis; by Dr. Senn on classification and surgical treatment of acute peritonitis; by Dr. Metchnikoff on the plague, and by Dr. Robert on the mutual relations of pathology and therapeutics.

The next international congress will be held at Paris in the summer of 1900, with Professor Lannelongue as President of the Committee of Organization.

THE SEAL FISHERIES.

DR. DAVID STARR JORDAN, Commissioner-in-chief of the fur seal investigations for the United

States, with Mr. George Clark, Secretary of the Committee, arrived at San Francisco on the 25th. Mr. Macoun, the Canadian Commissioner, had already left the Pribyloff Islands, and the British Commissioner, Professor Thompson, was about to leave on H. M. S. 'Amphion.' Mr. Lucas, of the United States Commission, remained behind for a week. President Jordan is reported in a press dispatch to have said that the breeding grounds showed a shrinkage of about 15 per cent. over the conditions of last season, and the hunting grounds a shrinkage of 33 per cent. This is about what was predicted by the American Commission last year. The primary cause of the shrinkage of females on the breeding grounds is the pelagic catch of last fall and this spring. To this is added the loss due to starvation of orphaned pups in 1894, which should this year have lived to give birth to their first pups. This starvation in 1894, affecting, as it did, in a like measure the male herd, is the cause of the diminution of the killable seals on the hunting grounds. The decline of the herd is everywhere more distinctly marked than it was last year, owing to the effects of the resumption of pelagic killing in Bering Sea after the *modus vivendi* of 1893. For 1898 the shrinkage will be still greater, through the destruction, in 1894, of unborn pups with females killed. Branding of young female seals, which will be begun after September 1st, will be carried on by Colonel Murray, chief agent on the islands, and E. F. Farmer, electrician. The skins of the branded cows which returned this year to the islands show clearly the permanency of the mark and its efficiency to render the skins unsalable, without injury to the animal or to the herd.

THE London *Times* has published a letter two and a-half columns in length from Mr. Herman Liebes, one of the lessees of the Prybiloff Islands seal rookeries, in which he presents the case for the United States in a temperate and reasonable manner, much more likely to prove convincing than the recently published letter of Secretary Sherman. The communication should make it clear to the ordinary reader that the decrease of the herd is not due to the loss of the seals killed on land, which are only young bachelors not serving harems, but to pelagic sealing, where at least 80 per cent. of those killed are females which are both pregnant and leave young to die of starvation on the islands. Since 1890 the annual catch of seals by the pelagic sealers amounts to an average of 88,916, as compared with an average of 15,770 from the islands.

THE MISSOURI GEOLOGICAL SURVEY.

THE following editorial comment appears in the *Journal of Geology:*

"The State of Missouri has recently had deep disgrace thrust upon it by the removal of the efficient director of the Geological Survey, and by the appointment of men to its care and conduct who possess, according to information that we deem trustworthy, not only no competency to perform their duties, but not even a plausible semblance of competency. These appointments have apparently no other motive than the conferring of personal or political favors. No causes of complaint, we are informed, were even alleged against the previous conduct of the Survey, or against the officials in charge of it. The scientific public has had ample demonstration of the vigor and energy with which the Survey has been prosecuted, the promptness with which its results have been published, and the adaptation of the work to the development of the economic as well as the scientific resources of the State. It appears, therefore, that the moneys appropriated by the State of Missouri for the laudable purpose of investigating and advertising its resources, and of informing its people concerning their own sources of material and intellectual wealth, are being virtually diverted from the purposes specifically indicated by the statutes of the State, and are being used for the personal and political interests of the Governor and his friends in the form of payment for worthless services. We are not sufficiently informed in the technicalities of law and the processes of the Courts to know how legal action in a case of this kind can be instituted and maintained, but if the appointees are as obviously incompetent as information indicates, they are simply consuming the funds of the State to no purpose save their own, and we think that an effort

should be made to procure a formal declaration by the Courts whether this is not a virtual embezzlement, and, if so, to secure the award of the proper punishment. If there is now no way of compelling a Governor to respect the laws of a State and the purposes of its statutes, a way should be provided."

GENERAL.

THE International Mathematical Congress, which closed its meetings at Zurich on August 11th, decided that its next meeting be held in Paris in 1900. A committee of five members was appointed to report on mathematical progress in different countries and to promote the establishment of mathematical departments in academic and other libraries. A resolution was passed favoring the institution of a central correspondence bureau in order to maintain closer relations between teachers and students of the higher mathematics in different countries.

THE attendance at the recent meeting of the French Association for the Advancement of Science at Saint-Etienne was smaller this year than usual, amounting to scarcely 400.

PRINCE LUIGI, of Savoy, and his party succeeded in reaching the summit of Mt. St. Elias at noon on July 31st. The altitude was determined to be 18,120 feet; no indications of volcanic action were found. It is said that the expedition under Mr. Bryant reached an altitude of 14,500 feet—the height reached by Professor Russell in 1891—and was compelled to return owing to illness.

IT will be remembered that Congress appropriated $5,000 for a continuation of the survey of the gold resources of Alaska, but the bill containing this item was passed too late to make it available this year. The expedition under Mr. J. E. Spurr will go next year, and it is proposed to ask for an increase of the appropriation to $25,000 in order that a complete survey may be made and a geological map of the region prepared.

PROFESSOR CORFIELD has been elected an honorary member of the Royal Society of Public Health of Belgium, of which he has been a corresponding member for some years.

PROFESSOR BELAJEFF has been appointed director of the Botanical Gardens in Warsaw.

IN addition to the degrees conferred on Lord Kelvin, Lord Lister and Sir John Evans by the two universities located at Toronto, McGill University will this week confer on them the doctorate of laws. The convocation of McGill University will be held in recognition of the meeting of the British Medical Association and will confer the degree on Dr. L. L. Barnes, President of the Association, and probably on others in attendance.

A SPECIAL number of the *Rendiconti della R. Accademia dei Lincei* announces, says *Nature*, the award of the following prizes, besides others for essays of a literary character: The royal prize for physics to Professor Adolfo Bartoli, of Padua, for his two monographs on the specific heat of water between the temperatures of 0° and 35°, and on the heat of the sun and for other investigations. For the ministerial prize for physical and chemical science eight competitors entered, and the judges have awarded a prize of 1,000 lire to Professor Carlo Bonacini, of Modena, for his essays on orthochromatic and color photography, and on the reflection and other properties of Röntgen rays; also awards of 250 lire each to Professor Carlo Cattaneo, of Turin, for his notes on the conductivity of electrolytes and on the velocity of ions, and to Professor Pietro Bartolotti for chemical investigations relating to the compound Rottlerine and other derivatives.

WE learn, with much regret, of the death of Professor J. E. Humphrey, which occurred about the middle of August at Jamaica, where he had charge of a biological expedition from the Johns Hopkins University. Professor Humphrey was a graduate of Harvard University and was a young man, having been promoted only last year to an associate professorship of botany at Johns Hopkins University. He had made important contributions to our knowledge of the algæ and in other directions, and was building up a strong department of botany in the Johns Hopkins University.

WE regret also to announce the death, at the early age of 23 years, of Mr. Joseph G. C. Cot-

tier, fellow of Columbia University. Mr. Cottier had been traveling in France since the first of July, and died from typhoid fever at Paris on the 17th of August. He was a student of exceptional ability in the mathematico-physical sciences and gave promise of a brilliant career.

THE deaths are also announced of Mr. Albert Marth, fellow of the Royal Astronomical Society and the author of many valuable contributions to astronomy, at the age of 69, and of Mr. S. E. Peal, of Assam, a writer on astronomical topics.

A CABLEGRAM to the daily press reports that the British steamer Windward, which left England on June 10th last, for Franz Josef Land, to bring back from the Arctic regions the members of the Jackson-Harmsworth expedition, who have spent three winters near Cape Flora, passed Aberdeen on Aug. 28th on her return trip and signalled that all were well on board. During the present summer the expedition was to make an attempt to reach the highest point north through an opening in Queen Victoria's Sea, the open water discovered by Jackson.

REUTER'S agency announces that M. Nossiloff, the explorer, has arrived at Tiumen from the Kara Sea. He has made important discoveries connected with intercourse between Siberia and Europe, especially a direct waterway which is considerably shorter than the old one and is not affected by the sea ice. M. Nossiloff also announces that he has investigated the hitherto unexplored Yalmal peninsula.

PROFESSOR W. W. CAMPBELL will have charge of the expedition of the Lick Observatory to India to observe the total eclipse of the sun on January 21st of next year. As we have already stated, this expedition has been made possible through the generosity of the late Col. C. F. Crocker.

THE Boston *Transcript* states that Mr. Edward Kemeys, the animal sculptor, will probably receive a commission for the decoration of the zoological park in Washington. It is proposed to decorate the park with bronze figures of Indians and wild animals, of life size or a little larger, to preserve the types of animal life which are rapidly vanishing. The Indians will be represented in some pieces as alone and in some pieces as riding or hunting the animals. The animals will sometimes be separate and sometimes grouped together, as in the case of a leopard killing a deer.

IT is reported that as soon as the new library of the Moscow University is completed, the well-known savant, Dr. Luginin, has promised to make it a present of his fine collection of books on chemistry, embracing 12,000 volumes, besides adding a sum of money for purchasing new books on that subject.

THE annual meeting of the corporation of the Marine Biological Laboratory at Woods Holl was held at that place on August 26th. The chief business was the election of a board of trustees and the enactment of some changes in the by-laws. Seventy members were in attendance. A resolution was adopted ratifying certain changes in the constitution proposed at a special meeting in Boston on August 16th. Among the more important amendments adopted were those providing that the number of trustees be increased from twenty to twenty-four, and that ex-officio members be made members of the board of trustees. Trustees were elected as follows: Clerk, Professor H. C. Bumpus, Brown University; Dr. E. G. Gardiner, Professor Clark, Williams College; Dr. J. P. McMurrich and L. L. Nunn, University of Michigan; Professor H. F. Osborn and Professor E. B. Wilson, Columbia; Professor William Libbey and W. B. Scott, Princeton; Professor W. C. Sedgwick, Massachusetts Institute of Technology; Professor Sydney W. Smith, Yale; Dr. William Trelease, Missouri Botanical Gardens; Professor W. P. Wilson, Philadelphia Museum; Professor B. Ramsey Wright, University of Toronto; Professor J. M. McFarlane and E. G. Conklin, University of Pennsylvania; Professor E. P. Mall, Johns Hopkins University; Professor E. L. Mark, Harvard; Samuel P. Scudder, Cambridge; Lawrence Minot, Boston; Professor T. H. Morgan, Bryn Mawr; C. G. Kidder, New York; Professor M. M. Metcalf, the Woman's College of Baltimore; Professor William Patten, Dartmouth; Professor D. P. Penhallow, McGill University.

Nature learns from the *Brisbane Courier* that Hon. R. Barr-Smith, of Torrens Park, South Australia, has offered to subscribe the amount

necessary for the establishment of a tentative meteorological station at the summit of Mount Kosciusko, in the southeastern extremity of Australia, at a height of about 8,000 feet. Mr. Wragge hopes that the comparison of the results with those obtained from low-level stations will insure a permanent observatory being established in the interest of Australasia.

M. JANSSEN was expected, says the Paris correspondent of the London *Times*, to leave Paris on August 21st to inspect his Mont Blanc observatory. The scientific caravan will start from Chamonix at the beginning of September to take meteorological readings at an altitude of 14,000 feet, the highest station in the world, and to study solar radiation. M. Perrotin, director of the Nice observatory, will, it is said, join the party in order to study the morning elongation of Venus and to ascertain the period of the planet's rotation. Foreign men of science wishing to make the ascent will enjoy the hospitality of the establishment.

AT the monthly general meeting of the Zoological Society of London, held on August 19th, at their offices in Hanover-square, it was stated that the number of additions to the Society's menagerie during the month of July had been 102, among which special attention was called to a young pair of Babirussas (*Babirussa alfurus*), from Celebes, presented by the Duke of Bedford; to an example of the thick-billed penguin (*Eudyptes pachyrhynchus*), from Stewart Island, New Zealand, deposited by the Hon. Walter Rothschild; and also to a very large example of Daudin's tortoise (*Testudo daudini*), deposited by the same gentleman. The President delivered the silver medal of the Society to Mr. Alexander Whyte, F.Z.S., in acknowledgment of the valuable services he had rendered to zoological science by the large collections he had made in every branch of natural history in British Central Africa, while acting as chief scientific officer to Sir Harry Johnston.

THE second International Conference on Railway and Marine Hygiene will, as we have already announced, meet at Brussels on September 6th, 7th and 8th. Several governments and societies have appointed official delegates, and numerous papers have been promised. There will be three sections: (1) Organization of the Medical Services; (2) Guarantees of Personal Fitness; (3) Hygienic Rules and Regulations. The officials and medical officers of foreign railway companies can obtain free passes upon the Belgian state railways. Dr. J. De Lantsheere, 56, Rue de l'Association, Brussels, will supply further information.

THE British Pharmaceutical Conference, which has recently concluded its sessions at Glasgow, will next year meet at Belfast, Dr. Symes, of Liverpool, being reelected President. One of the more interesting papers presented to the Conference was by Professor Atkinson, of London, showing that the people of Great Britain expend annually £3,000,000 on patent medicine. In 1872 the annual revenue from patent medicine stamps was £82,000; ten years later that amount was doubled, and in 1892 the tax produced £240,000. He thought that the government should exercise more control over the sale of these secret nostrums.

THE *Progrès médicale* publishes a somewhat extended account of the International Bibliographical Conference which met in Brussels on August 2d, 3d and 4th. A special discussion took place on the Dewey decimal system of classification, which was opposed by M. Funck-Brentano and defended by M. Baudouin and others. Dr. Haviland Field announced that the delayed *Concilium bibliographicum* for zoology would soon begin the issue of cards. M. Baudouin stated that within three years nearly 200,000 bibliographical cards with analyses, relating especially to the biological sciences, had been prepared for the Paris Institute of Bibliography.

MR. MOSES P. HANDY, special commissioner to the Paris exhibition of 1900, has gone to Paris to make arrangements for the space and location of exhibits from the United States. He is reported to have said before leaving that he thought 500,000 square feet of space would be required by American exhibitors, or more than four times as much as was in the exposition in 1889. The exhibits in electrical and railway appliances are expected to be especially complete. A thorough educational exhibit will also be prepared.

THE exhibition now open at Brussels contains a feature of interest to anthropologists. Two hundred natives of the Congo tribes have been brought from Africa and are exhibited in a replica of a Congolese village. The greater number are Batatelas, but other tribes are represented, including two of the forest dwarfs described by Stanley.

THE first number of the *Zoological Bulletin*, edited by Professors C. O. Whitman and W. M. Wheeler, of the University of Chicago, has now been published by Ginn & Co. The title page gives the names of seventy-three American students of the zoological sciences who have given their cooperation. This number contains articles by Edward Phelps Allis, Jr., on 'The Morphology of the Petrosal Bone and of the Sphenoidal Region of the Skull of Amia Calva;' by Charles W. Hargitt on 'Recent Experiments on Regeneration;' by Charles Lawrence Bristol on 'The Metamerism of Nephelis,' and by G. Baur 'On the Question of Intercalation of Vertebræ.' The number extends to fifty-three pages and it is expected to publish at least six numbers of this size yearly. The *Bulletin* has the same form and size of page as the *Journal of Morphology*, and will apparently differ from that journal only in that the articles will be as a rule shorter and not illustrated.

A QUARTERLY botanical journal, entitled *Bollettino del Reale Orto Botanico di Palermo*, will hereafter be published, under the editorship of Professor Borzi.

HENRY HOLT & Co. announce for early publication 'The Elements of Comparative Zoology,' by Professor J. Sterling Kingsley, of Tufts College; 'Laboratory Directions in General Biology,' by Harriet Randolph, instructor in Bryn Mawr College; an 'Outline Introductory to Kant's Critique of Pure Reason,' by Professor R. M. Wenley, of the University of Michigan, and a new and much enlarged edition of Hall and Bergen's 'Text-Book of Physics.'

WE are glad to note the full reports in the American daily press of the recent meeting of the British Association at Toronto, even though some of these papers did not mention the meeting at Detroit. We hope that all the papers will remember next year that there is an American Association for the Advancement of Science.

THE fourth International Scientific Congress of Catholics opened its sessions at Freiburg, Switzerland, on the 15th of August. Mgr. Dernaz, Bishop of Lausanne and Geneva, was the president of honor, and Baron Hertling, professor of philosophy in the University of Munich, was made president of the Congress. The Congress met in ten sections, and there were 500 members in attendance.

THE *Engineering News* Publishing Company have republished three articles on the floods of the Mississippi River contributed to the journal in the course of the past two years by Mr. William Starling, Chief Engineer of the Lower Yazoo Levee District. The articles describe the levees of the Mississippi river and the floods, especially that of 1897, and should prove useful in disseminating knowledge of the cause of the floods and the proper means to be used in combatting their ravages.

THE *Electrical World* reports a paper by M. Pierard describing an application of the phonograph in Spain. It appears that the telephone is there used in place of the telegraph, and it was found that the speed of transmission was greatly limited by the operators at the receiving end, who could not transcribe the messages sufficiently rapidly; at present the receiving operator repeats the message into a phonograph, from which it is then transcribed; this repetition is also heard at the transmitting end and therefore serves as a control for the correctness of the received message; the speed is 86 words per minute, which means double this amount if the return message is included. It is thought that this is the first time the phonograph has been put to this use.

A BRITISH Parliamentary paper has been issued given a report of the efforts to check the locusts in Cyprus during the past year. The High Commissioner, Sir W. J. Sendall, states that the system of purchasing eggs and living locusts, which has now been pursued for four years, has appreciably diminished the number of locusts.

THE first quarterly report, says the New

York *Medical Record*, since the appointment of medical inspectors of schools in this city has been made by Dr. Blauvelt, the chief medical inspector. The report includes a table showing the different kinds of diseases for which children were excluded from the schools. Parasitic diseases of the head appear to have been the most prevalent, 2,627 cases having been discovered among the children examined. Contagious diseases of the eye come next on the list, over 700 cases being reported. Skin diseases claimed 175 victims, and diphtheria 91. Measles was responsible for the exclusion from school of 51 children, and 20 cases of genuine scarlet fever were discovered. Croup was of comparatively rare occurrence, but 26 scholars were compelled to forego school attendance for a short time on account of whooping-cough. The report gives the number suffering from mumps as 117, and from chicken-pox as 93.

IT appears from an article in *Machinery* that the Stockholm Exhibition, which has attracted but little attention in the daily press, is of considerable scientific interest. The exhibition grounds cover an area of about 220,000 square yards—a space which is about doubled if the mountain plateau, which is given up to a realistic reproduction of Swedish country life from the Laplander's hut to the thriving farmer's homestead, with all the fauna and flora of the country, is added to it. The most imposing building in the grounds is the Industrial Hall, which is said to be the largest wooden structure in the world, a forest of about 34,000 trees having been used up in its elevation. The exhibits in this building are selections from the ordinary products of the industries of Sweden, Norway, Denmark and Russo-Finland. Not far from it is the Machinery Hall, and in close contiguity are mining exhibits, forest exhibits, electric works and numerous private pavilions illustrative of the industrial works of the country.

PROFESSOR RAPHAEL MELDOLA writes to the London *Times* regarding the case of death from an inflammable hair wash which has excited much discussion in Great Britain. "It is, of course, well known to those who are in the habit of dealing with low boiling-point liquids giving off inflammable vapors, such, for example, as ether, that the presence of a naked flame, even at a distance of many yards, is attended with great danger. But in the present case Professor Meldola corroborates by personal experience the contention of Lord Kelvin that an electric spark, although in itself feeble, is quite sufficient to ignite an explosive mixture of hydrocarbon vapor and air. Some years ago he was consulted by a manufacturer who had an extensive business in what is called the 'dry cleaning' of wearing apparel. In this process the goods, previously well dried, are immersed in a vessel of benzine, in which they are kept in motion by means of mechanical stirrers. In spite of every precaution to insure the absence of naked flames in the building in which the operation was conducted, fires were constantly occurring, and at one time the process threatened to become a failure on account of this apparently spontaneous inflammability of the hydrocarbon vapor. It was only when the possibility of the generation of electricity and the passage of sparks were suggested that precautions were taken to exclude air from the upper portions of the vessels and that the process became practicable. The experience afforded by this process points most conclusively to the correctness of the electric spark theory of the ignition, and on this ground alone the use of such inflammable hydrocarbons for cleaning the hair—apart from the very doubtful question of their efficacy—should be absolutely condemned."

THE Executive Committee of the International Medical Congress has followed the example of its predecessors at earlier gatherings in publishing descriptions of the medical institutions of the country. The *British Medical Journal* gives an account of one of these, containing a full description of the medical societies of Russia. The oldest Russian medical society was founded in Moscow in the year in 1804, and is still in existence. It is attached to the University of Moscow, and is known as the Physico-Medical Society. A year later the Vilna Medical Society was instituted; it also still exists, but owing to the chequered career of the University of Vilna (which was removed to Kief after the Polish rising of 1833) this society has lost something of its former prestige.

The institution of these two societies was almost coincident with the opening of the three Universities of Kharkof, Kazan and Vilna by the Emperor Alexander I. Before his reign there had been but one university in the Empire, that of Moscow. Towards the close of his reign, in 1819, still another university, that of St. Petersburg, was opened; and in the same year the Society of German Practitioners in St. Petersburg was formed. This was followed a year later by the formation of a similar society in Warsaw. A gap of over thirty years, corresponding to the reign of the Emperor Nicholas I., succeeded, during which but one medical society was instituted in Russia. This was the Society of Russian Practitioners in St. Petersburg. From the date of the accession of Alexander II. the number of these societies has rapidly increased. There are now no fewer than 120 in the whole of the Empire, the total capital of which amounts to over $600,000. The majority of Russian medical societies have libraries attached to them; while some have museums, laboratories and even free dispensaries.

UNIVERSITY AND EDUCATIONAL NEWS.

It is announced that M. Eulogius Georgieff, the founder of the Sofia University, who died recently, bequeathed 20,000,000 fr. to the Bulgarian government for public purposes, including 6,000,000 fr. for a technical school to be established at Sofia.

Mr. S. B. Brownell has presented Barnard College, New York, with a building for a dormitory to cost $150,000, which will be erected at once.

The endowment left by Patrick B. O'Brien, of New Orleans, for establishing chairs of chemistry, of physics and of Roman law in the Catholic University of America will be available this autumn. The Rev. Father W. J. Kirby has been appointed professor of sociology.

A committee of the Trustees of the University of Missouri has been appointed to investigate the political views of Professor C. H. Hicks, since 1892 professor of political economy in the University. The report of the committee will probably result in the removal of Professor Hicks, and it is said that Dr. W. G. Brown, professor of chemistry, is likely to share the same fate.

The Council of the University of Lyons has devoted the sum of 42,000 fr. to complete the construction of the laboratory of biology of Tamaris, near Toulon, and it is expected that a sum will be appropriated to the support of the laboratory.

The School of Applied Chemistry, founded last year under the auspices of the faculty of science of the University of Paris, has celebrated its first anniversary. M. Darboux presided, and an address was made by M. Friedel, director of the laboratory.

The University of Berlin offers holiday courses for teachers of science in the higher schools from the 29th of September to the 9th of October of the present year. Lectures will be given by Drs. van't Hoff, Dames and other leading professors, and excursions and visits of scientific interest have been arranged.

Dr. Kihlman has been appointed associate professor of botany in the University at Helsingfors. Dr. Theodor Petersen and Dr. Josef Epstein, of the Physical Institute of Vienna, have been appointed to professorships. Mr. Stanley Dunkerley, of the department of applied mechanics, Cambridge, has been appointed professor of applied mechanics at the Royal Naval College, Greenwich.

DISCUSSION AND CORRESPONDENCE.

'THE PRESENT EVOLUTION OF MAN.'

In Science of July 2d, pp. 33–35, Professor T. D. A. Cockerell published a kind and appreciative review of my book 'The Present Evolution of Man,' for which I am more than grateful. He disagreed with me, however, as to several matters, and as on these precisely I have failed to carry conviction to many critics I am forced to believe either that I am wrong or that my explanations have not as yet been adequate nor sufficiently clear. I would fain hope the latter, and therefore am glad to seize the opportunity Professor Cockerell's review affords of making some reply in the pages of Science.

Professor Cockerell does not entirely agree with my theory of retrogression. Put very

briefly, that theory is as follows: It is known that the ontogeny recapitulates the phylogeny, though in a rapid, blurred and indistinct way.* In other words, almost every individual recapitulates the traits of all his ancestors, beginning with those of the first (as, for convenience, we may call the unicellular organism) and ending with those of the last. I use the word 'almost' because, though the earlier stages must, of course, be recapitulated, for otherwise the individual would not develop, yet sometimes (indeed often) the very last steps made in the evolution of the race fail to be reproduced by the individual in his development. He then resembles some remote ancestor more than he does his parents, and presents, in fact, an example of what is known as atavism. When the evolution of the race has been rapid, reversion to any given ancestor results, of course, in a much greater and more observable degree of retrogression than when the evolution has been slower, and therefore, while offspring of race horses often exhibit far-reaching reversion towards the ordinary horse, and while the seedlings of various garden plants (apple, peach, rose, etc.), which have been evolved under excessively stringent selection, generally revert to the ancestral type, the offspring of wild plants and animals generally 'breed true.'

An individual may vary from his parent in two ways—towards the ancestry when some of the last steps made in the phylogeny are omitted in his ontogeny, or away from it, the former variation being atavistic, the latter evolutionary; and so far as we are aware the chances of his doing the one or the other are equal. But while every variation towards the ancestry, that is, every failure to repeat in the ontogeny the last steps made in the phylogeny, produce atavistic retrogression, every variation from it need not be an extension of the previous evolution; it may constitute a reversal of it (as will be seen presently) or be in some other different direction, whence it follows that in the absence of selection a species must always undergo retrogression.

Up to this point, or nearly up to it (for as to this I am not very clear), my critic and I seem to be in agreement; but beyond this we differ, for while he thinks that such atavism can result in very limited retrogression only, I am of the opinion that in the entire and continued absence of selection it must result in absolutely unlimited retrogression. Before dealing with his objections I ought to say that in my book I quite reject the Lamarckian doctrine of the transmissibility of acquired traits, and since Professor Cockerell is good enough to say that he regards the arguments there used as conclusive, the matter is not in dispute between us. Moreover, he seems to agree with me in attributing evolution to the accumulation of small 'normal' variations, not to the accumulation of great and abnormal variations, for the reason that the latter tend to be swamped, owing to their infrequency. I should also make it clear that by atavism I do not necessarily mean atavism of the whole organism. Such wholesale reversion to the ancestral type must be extremely rare in the case of all species slowly evolved under the ordinary conditions of nature; it occurs only, so far as I am aware, in such species as have evolved under very stringent artificial selection. Under natural conditions an individual may exhibit evolution in some particulars and atavistic retrogression in others, but these latter, owing to the slowness of the antecedent evolution, must generally be minute in amount, and, therefore, when associated with evolutionary changes, unrecognizable in the individual, though recognizable after the lapse of generations in a line of individuals. Thus, while selection may result in evolution in the legs of a bird to which flight has become useless, atavistic reversion in the absence of selection as regards them would result in the retrogression of its wings. But here again, the wings, being complex organs, would not equally retrogress in all their parts, and, therefore, would never very closely approximate to the ancestral type.

Professor Cockerell says: "I cannot see, with Mr. Reid, that there would be unlimited atavism, because when the atavistic changes had proceeded from B to A *the B features would become ancestral* and a new atavism from A to B would appear." (The italics are mine.) It is

*I have given reasons why the recapitulation is blurred and indistinct, but these need not detain us here.

this sentence which leads me to suppose that I have not adequately explained myself, for clearly Professor Cockerell does not understand my theory as I understand it. Supposing, as regards any character, A B C D represent a line of individuals, then, if D reverts to B, that is, if D varies from C so that in his ontogeny he repeats the life history of the race only up to the point reached by B, omitting the additional characteristics of C, my contention is that C disappears altogether from the series, which, from the point of view of heredity, becomes A B D and, therefore, if the characters of C ever reappear in E, or any subsequent member of the series, they must do so (as they did in C's case) as a result of evolution (variation away from the ancestry), not as a result of retrogression, of atavism (*i. e.*, variation towards the ancestry).* To test the truth of the theory we must consider a species in which evolution has been very rapid, as in that case atavistic changes can easily be observed with comparative ease; for example, any one of the various garden plants which are propagated by means of slips, it being probable that but a few seminal generations intervene between these widely divergent types and the ancestral wild varieties. The seeds of such a cultivated plant usually give origin to plants, which, in the great majority of instances, resemble much more nearly the wild than the cultivated variety. Now, if Professor Cockerell is right, the continual seminal propagation of such reverted plants should often result in a 'reversion' to the cultivated type; whereas, if I am right, this 'reversion' should never occur, since (for purposes of heredity) the cultivated variety has been eliminated from the ancestral line. Such reappearance would purport, therefore, not reversion, but a fresh evolution, which evolution would be too great to be accomplished in a single generation. So also the race horse, in the absence of selection, would revert to the ordinary horse, after which a race horse should be as rare among the progeny as it is at present among the progeny of ordinary horses.

It follows as a logical conclusion from the foregoing that cessation of selection, as regards any structure or character, during unlimited time must result in unlimited atavism. First recent ancestors would be approximated to, then ancestors more remote, and lastly that remote ancestral condition when the structure or character did not exist. It would then disappear as utterly as have done, from this cause, the limbs of serpents. In fact, atavism effects the same result as disuse is said to do by Neo-Lamarckians, and, unless we accept the Lamarckian doctrine, I confess I am unable to perceive any other probable reason for retrogression.

Professor Cockerell further writes: "The germ, it must be supposed, contains units representing many phases of existence, while others are new. When one of the latter develop we say the variation is a progressive one; when the former develop we call the result atavism. It is reasonable to suppose that environmental and germinal selection are the factors which determine which of its possible developments the germ shall undergo." Here, again, is proof that I have not made myself clear on this point to Professor Cockerell. He has been kind enough to speak with some approval of my theory, but he has not perceived that it is absolutely incompatible with the theory of germinal selection. Surely in the present state of our knowledge it is too much to affirm that the germ *must* contains *units* 'representing phases of existence.' During the ontogeny many phases of existence are represented in fleeting but orderly succession, but again, surely it is not essential to suppose that the development of each is due to one or more *units;* and, moreover, does not the regular recapitulation of the phylogeny during the ontogeny negative the idea that any 'units' are 'held over?'

I must be brief in my comments on the rest of Professor Cockerell's review. He says that in considering man's present evolution I have neglected to take into account what Mr. B. Kidd has called 'social efficiency.' If he turns to my work (pp. 178–200) he will find that I have not altogether neglected the matter. Briefly, I have attributed differences in social

*For the sake of simplicity I do not here consider such a case as when D repeats the life history up to C and *then* reverts *back* to B, but it is dealt with to some extent in my book, and the process is of importance when considering the phenomena connected with 'reversed selection.'

efficiency to differences in acquired mental characters, that is, to differences in education. Mr. Kidd attributes social efficiency, which he derives from the greater or lesser development of the altruistic feeling, to natural selection; but natural selection implies elimination of the unfittest, and he has failed to record a single death as due to the absence of this feeling in him who perished and the presence of it in him who survived. If it be maintained, as is sometimes done, that 'social efficiency' has been evolved, not through selection of individuals, but through selection of communities, then I can only say that such a contention appears to me to involve a complete misconception. Evolution can result only from the selection of individuals, never from the selection of communities; except, indeed, in the case of such communities (*e. g.*, ants, bees, terits) as are the progeny of a single pair of individuals, when the parent individual is selected in the person of the progeny. Supposing a superior community (of men, for instance), without individual selection within itself, causes the elimination of an inferior community, then, as a consequence, the former spreads, but does undergo evolution. Its superiority (if inherent, and not acquired) arises from an antecedent selection of individuals within itself. Professor Cockerell says that sanitary arrangements 'do select the citizens of one town, state or country as against others, or those of the rural districts as against the towns.' But surely sanitary arrangements do not come under the head of human evolution, but under what has been called 'Evolution in the Environment.' The knowledge of it is acquired. If New York now values sanitation more than it did fifty years ago, or more than Baltimore does at the present time, is this not due, beyond doubt, to a difference in education (*i. e.*, acquired mental characters), not to an inborn intellectual difference?

I now come to the last of Professor Cockerell's objections and I wish exceedingly I had more space to deal with it. I have shown that certain powerful narcotics (*e. g.*, alcohol and opium) are great causes of elimination; that races (*e. g.*, Greeks, Italians, South Frenchmen, Spaniards, Portuguese) which have long possessed a cheap and abundant supply of alcohol, for instance, are the least prone to excessive indulgence of all races on earth; that other races, (*e. g.*, Anglo-Saxons, Scandinavians, Russians, etc.), which have had a less extended experience are more prone to intemperance; that yet other races (*e. g.*, savages of all kinds, whether inhabiting the frigid, the temperate or the torrid zones), who have had little or no experience of alcohol, crave for that narcotic so intensely that, in the presence of an abundant supply and the absence of prohibitory laws, they perish of excessive indulgence; and have argued, firstly, that the craving for narcotic indulgence was inborn in man as a by product of mental evolution;* secondly, that the Italian, for instance, is more temperate than the American Indian, as a result of natural selection, *i. e.*, alcoholic selection; and thirdly, that to render a race more temperate we must eliminate, not drink, but the excessive drinker, for compulsory temperance must lead to the survival of the unfit and consequent retrogression of the race to the ancestral type, when the craving was stronger than it now is in a race which has undergone alcoholic selection.

Had I proved my facts and used this line of argument as regards any physical structure I think all the world would have agreed with me; but, because I dealt with the burning question of intemperance, I have met with numerous objectors ranging from a clerical gentleman, who found distinct points of resemblance between Satan and me, and argued that, *therefore*, my theory 'must be a lie,' through Professor Ray Lankester, who, while admitting the truth of the theory, apparently thought that a tendency to get excessively drunk might be necessarily correlated to extremely valuable quali-

* Just as the paresis which accompanies excessive fear is inborn, *e. g.*, in frog when attacked by snake, as a by product, a correlated variation, of the life saving faculty of fear. Of course, I do not mean that an American Indian, for instance, who has never tasted alcohol, craves knowingly for it; I merely mean that he has an inborn love for such feelings as are induced by deep indulgence, just as he has an inborn love for such feelings as may be induced by eating a delicious food. Till he tastes a peach, for instance, of course he does not knowingly crave for it, yet nevertheless the love for the peach is born and in like manner is that for alcohol.

ties, up to Mr. Alfred Russell Wallace and to Professor Cockerell, who thinks "that the human race has no natural craving for alcohol at all, but it has a craving for excitement and other states of mind which may be induced artificially, and that when the natural exercise of highly valuable faculties is denied, as is so often the case in our present civilization, artificial means, often highly injurious, will be resorted to." But it is the absolute savage who is most prone of all races on earth to excessive indulgence, and surely, living, as he does, in a 'state of nature,' the natural exercise of 'highly valuable faculties' is not denied to him. Moreover, if Professor Cockerell is right, what is the difference between the civilization of the South and North of Europe, which permits in the former case the natural exercise of valuable faculties, but forbids them in the latter, for the north Europeans are much more drunken than the south Europeans.

Let the reader think awhile. Why does he not get drunk? Is it because he constantly resists the craving, or because the craving does not exist in him? I think he will say, 'the latter.' But has he no acquaintance, reared and living under much the same conditions, who drinks, to excess, though all his interests call him to abstain? I think he is sure to have such an acquaintance. Now, in this respect nations like the Italians or the Spaniards are mainly composed of individuals like my reader, while nations like the American Indians or the native Australians are mainly composed of individuals like his unfortunate acquaintance.

Here is a significant fact: old records seem to prove that the classic races were anciently much more intemperate than at the present time. For instance, the temperance question was formerly a burning one in Greece, where unhappy Helots were made to furnish 'awful examples' to the aristocratic youth. Here is another: the deadly narcotic opium has been in use for some hundreds of years in India, and never or very rarely does a native of that country take it to excess; it has been in use for about two hundred years in China, and most of the Chinese are temperate, though some take it to excess; it has been recently introduced into Burmah, and, practically speaking, all Burmans take it to such excess that they perish of it, and, therefore, in their own country the English have forbidden the use of opium to Burmans alone, while permitting it to all other peoples, just as in Canada alcohol is forbidden to the aborigines alone. Here is a third: tobacco causes little or no elimination, and, therefore, the craving for it is as strong in races that have longest used it as among races to which its use is comparatively strange.

G. Archdall Reid.

Louthsea, England.

AMPHIBIA OR BATRACHIA.

Professor Burt G. Wilder has made some remarks in the last number of Science (August 20, 1897) about the French word *Batraciens*. He says: "Dr. Baur shows that the French word *Batraciens* was applied to the frogs, toads and salamanders by Brogniart in 1799, and that the Latin forms *Batrachii* and *Batrachia* were not introduced until 1804 and 1807, by Latreille and Gravenhost. But does not Dr. Baur lay undue stress upon the distinction between the French and the Latin form? *Batraciens* is not (like *crapaud*, etc.) a vernacular word; it is the French form, or, galloparonym (!), of the Latin *Batrachia*, and the employment of the former would seem to constructively sanction the use of the latter." Professor Wilder 'as a teacher of zoology, but without claim to expert authority upon taxonomic points,' seems to be absolutely ignorant of the fundamental rule in nomenclature (published in all Codes of Nomenclature), that all vernacular names, of genera, families, orders, classes, even if formed from a classical root, are never accepted. Such vernacular names have especially been used in France by Cuvier, Lesson, de Blainville and notably other French writers of the early part of the present century. Such names have in many cases been later adopted into the science under a proper classical form, and should take date only from this later introduction. I should like to recommend to Professor Wilder the study of 'The Code of Nomenclature adopted by the American Ornithologists' Union, 1892.' This code is followed by all American naturalists. The case of *hippocampus* referred to by Professor

Wilder has nothing to do with zoological nomenclature.

G. BAUR.

THE SOURCE OF METENCEPHALON AND OTHER LATIN NAMES FOR THE SEGMENTS OF THE BRAIN.

TO THE EDITOR OF SCIENCE: In my paper, 'The definitive encephalic segments and their designations,' read before the Association of American Anatomists last May, were offered objections to the action of the Anatomische Gesellschaft* in designating the region between the cerebellum and the myel (spinal cord), not by *metencephalon*, as in the last three editions of Quain's 'Anatomy,' but by *myelencephalon*. This last was proposed by Owen for the entire neuron (central nervous system) in 1866 or earlier, and, so far as I know, its application to a single segment was made by Huxley in 1871. Before printing the paper above named, I desire to ascertain when and by whom that region of the brain was first called metencephalon; incidentally, also, the source and date of the other words, *prosencephalon*, *diencephalon*, *thalamencephalon*, *mesencephalon* and *epencephalon*, that have been offered as equivalents for von Baer's names, *Vorderhirn*, *Zwischenhirn*, *Mittelhirn*, *Hinterhirn* and *Nachhirn*. Information through your columns or directly will be very welcome.

ANDRÉE'S NORTH POLE BALLOON VOYAGE.

IN SCIENCE for August 20th, p. 291, occurs a copy of a telegram purporting to come from Dr. Nils Ekholm regarding the Andrée balloon which is attracting so much attention. One serious error in the transcription should be corrected. It is stated that the balloon at the start rose to a height of 15,000 to 25,000 ft. The original may have been 150 to 250 metres (490 to 820 ft.), but could not possibly have been as given. To ascend 25,000 ft., over 3 tons of ballast would have to be thrown out, and this, of course, is not thinkable. At 25,000 ft. two-thirds of the gas would have been lost and the voyagers would have been in great danger of freezing to death.

It is a little difficult to understand Dr. Ekholm's figures. Admitting that 1,800 cubic feet of gas leaked out each 24 hours, entailing a loss in buoyancy of 123 pounds, as he gives it, there should still be enough gas for over 70 days, instead of 22 to 24 days, as given. A leakage of 1,800 cubic feet would be about 1%, which is not excessive, though about 2 times as much as was expected. There are very few balloons built that have a leakage less than 3%. The very best 'cæcum' balloons ever made have a leakage of ½% in 24 hours. The total buoyancy of the gas was 12,000 pounds. The 3 men would weigh 500 and the balloon probably not over 1,700 pounds. Very tight balloons have been made in this country that would weigh for the same size about 900 pounds. This would give 80 days' flotation. It is probable that the computation calls for even a heavier balloon and also for carrying the car all the way. It is customary, however, to prepare the car so that it can be used as ballast and at the last use the ring of the balloon.

It is a great pity that more experience was not gained in a long voyage before attempting the extremely hazardous voyage to the Pole. The fact that the balloon was beyond control at the very start is very significant. It is doubtful if any aëronant living can release safely a balloon of 170,000 cubic feet capacity in a twenty-five-mile wind. Those who were present at St. Louis on June 16, 1887, will remember the extreme difficulty experienced in sending off the World balloon 160,000 cubic feet in a twenty-mile wind.

If plans had been made to keep the balloon at 6,000 feet or so the success of the voyage would have been better assured. By using a small pilot balloon it would have been easy to send the overflow into the smaller balloon and, after the larger had leaked out enough, the gas in the smaller balloon could have been sent into the larger and the smaller used as ballast. At 6,000 feet the danger of rain and sleet freezing on the balloon would have been avoided and the currents which are far steadier and more rapid would have reduced the voyage by

one-half or even one-third. It is not generally known that this country holds the record for a long-distance voyage.

On July 1, 1859, La Mountain and three others sailed from St. Louis, Mo., to Henderson, N. Y., 870 miles in nineteen hours. Such constancy and velocity of air currents is seldom thought of and could have been found only, as in this case, at a height of 6,000 to 8,000 feet.

The balloon route would seem the ideal method of reaching the Pole and the French are already planning for such a voyage in 1898. Let them first bring their balloon to this country and make the Atlantic voyage in the track of steamers where the least untoward event will not be absolutely fatal. Also, by all means, let the balloon be placed at a height of at least 6,000 feet. It is just as easy to keep a balloon there as close to the earth. At Mt. Washington (6,300 feet) there have been frequent cases of west winds of 100 miles and over per hour for 36 hours, and this would mean less than 40 hours for the trip.

Of course, the great question is as to the occurrence of storm and high-area conditions at the Pole similar to those in more southerly latitudes, and the evidence from weather maps made near the Pole seems to show a great similarity. If so, any steady wind near the Pole would give a straight course to the Pole and the same wind would give a straight course back to civilization. It is a pity that with so much interest centered in this enterprise there should be so many fakes of carrier pigeons, etc., started. It is very rare, indeed, that a carrier has been known to fly 1,000 miles and then only after being taken over some part of the course half a dozen times. For a carrier to go 1,500 or 2,000 miles is an unheard-of feat.

SCIENTIFIC LITERATURE.

Agriculture in Some of its Relations with Chemistry. By F. H. Storer. New York, Charles Scribner's Sons. 1897. Pp. 1901. $5.00.

The new edition of Storer's 'Agriculture' is in three volumes; it is accompanied by a very full and well-arranged index, which adds to its value as a reference work. The author is modest in his title, for not only is agriculture dealt with in its relations to chemistry, but very largely in its relations to the allied sciences, physics, physiology, botany and zoology.

For example, the contents of Volume I. include thirteen chapters, and in the first six the relations of physics and plant physiology to agriculture are discussed quite as fully as are the relations of chemistry in the remaining chapters. In Chapter III. 'Relations of Water to the Soil' is discussed, and in Chapter IV., 'Movement of Water in the Soil;'' Chapter V. is devoted to a study of the principles of 'Tillage,' and Chapter VI., 'Implements and Operations of Tillage.' In these branches chemistry is not the primary science involved. In Chapter I. 'The General Influence of Soil and Air to the Plant' is treated, and in Chapter II., 'The Atmosphere as a Source of Plant Food.' In the discussion of these subjects the importance of the relations of plant physiology are fully recognized.

I note the above in order to show the general scope of the work; it is not limited to a setting forth of the relations of chemistry, as it could not well be and give a broad view of scientific agriculture.

That the author regards the question of manure to be of very great importance is shown by the elaboration of the various topics entered into, especially concerning the sources of supply, the modes of action and methods of using the various products. Seventeen chapters, seven in Volume I. and ten in Volume II., aggregating over 750 pages, are devoted to this one branch of scientific agriculture, and in which chemistry *is* the primary science involved.

His method of treating of the artificial fertilizers is worthy of particular mention. Not only is the theoretical consideration concerning the composition and character of the various fertilizing materials and their modes of action given, but numerous experiments from leading authorities are cited, thus putting before the student the original source of the information; a point often greatly desired by those who have not had a broad training in these lines, and

are thus not fully acquainted with the literature of the subjects involved.

Particular attention should also be called to Chapters XVIII., XXVI. and XXVII., concerning 'Humus or Vegetable Mould,' 'Lime and Lime Compounds,' and 'Sodium Compounds.'' It is eminently desirable that the information given in these chapters should be more generally disseminated, in view of the useless dissertations on these subjects by irresponsible writers. Humus, particularly, is an engaging topic for discussion by those who do not understand what it means. The same is true of lime—fruitless discussions are entered into, largely because of the lack of knowledge concerning the principles involved. So, too, with the matter of sodium as a fertilizer; papers teem with articles that are calculated to lead astray rather than to fix valuable truths in the mind of the farmer. Such articles also seem to possess a peculiar attraction for the general reader, and the result is 'confusion worse confounded.'

In Chapter XV. of Volume II. the subject of 'Symbiosis, or Blended Growth,' is discussed in the light of the recently acquired facts concerning this very important subject

That the legumes may and do, under proper conditions, use atmospheric nitrogen, is one of the most important recent discoveries in agricultural science, and the matter in its scientific and practical relations is fully and clearly set forth.

Volume III. contains fourteen chapters. It treats more particularly of 'The Theory and Practice and Systems of Crop Rotations,' the principles involved in and the advantages of 'Irrigation,' 'The Use of Sewage,' and 'The Growth and Management of Cereal Crops,' hay and pastures and the 'Making of Silage.' In the handling of these subjects, not only are the principles of chemistry as applied to agriculture well traced and made plain, but important practical suggestions are made concerning the economical principles involved in the general management of farms and in the growth of the various crops. The chapter on irrigation, while written from 'the point of view of a New Englander,' is, in view of the necessity of fully utilizing the natural advantages of the East, very timely, since it calls attention to the subject and points out conditions which are necessary for successful irrigation. Much of historical interest is included, also. The chapter on 'Ensilage'—it should be 'Silage'—is also up-to-date and includes much of value not otherwise readily accessible.

On the whole, the work may be regarded as of very great value to students and farmers alike, and should be in the library of every progressive man. The reader or student who takes up these volumes cannot fail to be impressed not only with the vastness of the subject included under the title 'Scientific Agriculture,' but also with the very great necessity to farmers of the present day of a knowledge of the principles upon which agriculture is based.

It may, perhaps, seem strange to the average person, that so little of the work of American investigators is cited by the author, for, with the exception of the Chapter on 'Silage,' comparatively few references are made to experiments conducted in this country. This is, doubtless, due in part to the fact that our experiment stations are comparatively new institutions, and that thus far but few workers are engaged upon purely scientific problems; much, however, of scientific interest, and that would add to the value of the work, has been overlooked.

While the work is a veritable storehouse of information, there is a profuseness of statement and an elaboration of details which seriously detracts from its usefulness, either as a ready work of reference or as a text-book for the student or progressive farmer. Sharp, clear-cut statements of principle and of fact are attractive, and appeal quite as strongly to the general reader in works of a scientific nature as in other lines of literature.

RUTGERS COLLEGE,
NEW BRUNSWICK, N. J.

The Sense of Beauty, being the Outlines of Æsthetic Theory. GEORGE SANTAYANA. New York, Charles Scribner's Sons. 1896.

So much has been written upon the theory of Æsthetics which, from the point of view of the trained intelligence, is nonsense pure and simple that the appearance of so noteworthy a

book on the subject as that of Dr. Santayana ought to receive special mention in the pages of SCIENCE. For the scientific man must ever have before him as a warning, the sad loss of the æsthetic and literary sensibilities which befell Darwin—a loss which, however much one may be given up to an absorbing pursuit, it is easily possible to prevent if one will but give oneself now and then a full and unrestrained bath, of short duration it may be, in some form of æsthetic enjoyment or of æsthetic speculation. If the college professor can spend his summers in painting pictures, as more than one college professor in this country is known to do, he will be reasonably sure to keep himself a happy human being and at the same time to detract nothing from his sum-total of scientific energy. But without so much of a draft upon time and native powers as this implies, a degeneration of the æsthetic faculty can be warded off in simpler ways—by a few months' absorption now and then in European picture galleries or in Swiss mountain scenery, by attaching to oneself a few artist friends if opportunity permit, by a breath of vigorous English poetry before going to sleep at night, or by many another similar device. While Darwin is the great example of a confessed total atrophy of the æsthetic feeling, it cannot be denied that in England the scientific man is more frequently a man of wider culture and experience, that scientific society is less likely to be unbearably monotonous and dull, than in this country. No doubt there is a larger number of cultivated families in England out of which the scientific contingent may be recruited, but at the same time that peculiar American energy which enables many a poor boy to become a master in his chosen field of intellectual activity would enable him at the same time to do something more, if he were once to be convinced that the charm of living, and hence the only pleasure of living (aside from the low pleasure of a gratified ambition), is indissolubly connected with the development of the æsthetic sensibilities.

The point to be particularly insisted upon in connection with the book before us is that *reading about art* is sometimes no less effective than the work of art itself, not only in turning the attention to such appeals to artistic enjoyment as may fall within one's field of view, but also in producing an actual sharpening of those senses through which the art appeal is made.*

The follower of scientific pursuits will do well, therefore, if he does not fail to make himself acquainted with so keen and luminous an imparting of the nature of the feeling of the artist in the presence of the work of art as this book contains.

In gratitude for so much that is of value, the dispassionate reader will doubtless be able to overlook, or at least not to lay up against the author, the passages of a silly and sickly sentimentality, in which he maintains, that a zealous philanthropy and a pure love of science are but the fires of stifled sexual passion bursting out in a different form. A thesis so wide of the mark as this will be as repugnant to the true artist as it is to the clear-brained psychologist, and it will find its audience only with those who have been made blind to the healthy aspects of human life by the novelist of degenerate France.

C. L. F.

BALTIMORE,

* The present reviewer has a definite experience to communicate upon this point. Upon one occasion I had spent the whole afternoon in reading Charles Auchester (a marvellous book, when we consider that its author was only seventeen years old when it was written). I had been completely absorbed in the book, and had had no other thoughts for several hours. I then dressed quickly, and went out to dinner. The people at the dinner table were all wel known to me and I was not expecting anything unusual, but I found to my surprise that I heard them with new ears. I perceived that their voices had a thousand shades of meaning, revealed a thousand qualities of character and mood, that I had hitherto been deaf to. It even seemed to me a kind of immodesty to perceive their bare souls so plainly as I now did through their voices. I had to use, in order to describe this experience, phrases similar to those which are common for vision—my ears were opened; I felt that hitherto I had heard as through a fog dimly; my ears had become unveiled; it seemed as if a lot of obstructing layers had been peeled off from my organ of hearing. If I could only have kept up this high tension of the aural intelligence and the aural sensitiveness I should, no doubt, have become easily a person of better capacity for the enjoyment of music that I am now, as well as a keener critic of my fellow men.

THE MEETINGS OF THE AMERICAN AND BRITISH ASSOCIATIONS FOR THE ADVANCEMENT OF SCIENCE.

THE current progress of science and the activity of scientific thought in the civilization of the present day have been signalized in a noteworthy manner by the meetings of the American and British Associations for the Advancement of Science, and of kindred societies, held recently at Detroit and Toronto. As might have been expected, the meeting of the American Association at Detroit and that of the British Association at Toronto both fell somewhat short of the average numbers in attendance; but, on the other hand, both meetings were above the average in the number and quality of the addresses and papers presented and in the enthusiastic interest of the participants. The meetings of the affiliated societies were marked likewise by the high order of the papers read and by the profound interest of the discussions and conferences of the members and foreign guests in attendance. To one present at these meetings and cognizant of the zeal, fidelity and good cheer of the delegates assembled, it would hardly appear that scientific men are seriously disturbed by those publicists who think that science will soon overreach itself, if it has not already fallen into 'bankruptcy.' Nor could one who heard a number of the scholarly addresses delivered at these meetings, addresses remarkable for their literary finish as well as for the value of their contents, entertain the scholastic fear that the perfume of the

Attic violet is likely to be stifled by the mephitic odors of the laboratory.

The sessions of the American Association at Detroit were held during the week beginning August 9th, under the favorable auspices presented by a beautiful city and by the admirable facilities of the Detroit Central High School. The ample accommodations of this building, the generous hospitality of the citizens of Detroit, and the assiduous labors of the local committee, afforded an ideal environment, and one to which the Association will doubtless be pleased to return in due time.

Owing to the death of Professsr E. D. Cope, the duties of the retiring President fell upon Dr. Theodore Gill; while the absence, by reason of illness, of the President-elect, Professor Wolcott Gibbs, threw the labors of the presidency of the Detroit meeting on the next senior Vice-President, Dr. W J McGee. It was commonly and justly remarked that the fidelity and ability with which Dr. Gill and Dr. McGee executed the arduous trusts thus unexpectedly brought upon them contributed in a most marked degree to the success of the meeting.

The opening session of the Association was held in the spacious auditorium of the high school and proceeded with the usual invocation and addresses of welcome from representatives of the city. Perhaps there is still need of this formula in introducing to a community a national scientific organization whose work and aims are but little known. But its use sometimes leads to inconsistencies and absurdities which are very depressing to men of science. The invocations are not infrequently tantamount to an apology for the existence and to a plea for the toleration (within due limits) of science which are at once needless and undignified; while the labored efforts of unscientific men to welcome science as the 'handmaid of religion' are often painful episodes in an otherwise pleasant greeting.

In spite of the small attendance the meeting must be regarded as one of the most successful in the history of the Association. This happy outcome may be ascribed to a number of causes. Among these may be mentioned the carefully prearranged programs of the sectional committees; the continuity of the meetings, which now run from Monday to Friday without interruption by excursions, etc.; the joint meetings of Sections C and E with the American Chemical Society and with the Geological Society of America, respectively; and the accessions of fresh enthusiasm from the younger members of the Association. The presence and participation of a number of foreign guests added greatly also to the interest of the sessions. The presence, likewise, of a number of past Presidents of the Association was an inspiring feature which ought to be more prominent in the future than it has been in recent years.

As usual, the labors of the Council were wearisome, consuming about eighteen hours per day throughout the week, and leaving but little time for science to those charged with official duties. Some constitutional amendments whose object is to shorten and simplify the business affairs of the Association were adopted. Other changes looking

toward the same end must be considered, doubtless, in the near future, especially in connection with the question of the relations of the Association to the vigorously active affiliated societies.

The election of Professor F. W. Putman to the presidency of the Association was the highest tribute that could be paid him for his long and indefatigable labors as Permanent Secretary. The cordial unanimity of this election was fitly supplemented by the hearty acceptance of the graceful invitations of Boston to hold the semi-centennial meeting of the Association in 1898 in that city. All interested in the advancement of science in America should aim to be present at this next meeting. The Association has a great work to perform, and every friend of science should aid that work by his presence and good fellowship at the meetings even should he not contribute to the formal proceedings.

On Monday, Tuesday and Wednesday, August 16th–18th, the American Mathematical Society and the American Society for the Promotion of Engineering Education held their meetings at Toronto. The spacious accommodations of the beautiful buildings of the University of Toronto were placed at the disposal of the societies, and the University authorities, individually and collectively, were most gracefully attentive to the needs and pleasures of the delegates. The rapid growth and the productive activity of these societies—each now counting more than 200 members, and each printing 300 to 500 octavo pages of proceedings—are at once surprising and gratifying. Their history, which cannot be entered into here, is similar to that of the Geological Society of America. Their work is in many respects allied to that of the American Association for the Advancement of Science, and a closer affiliation with the latter through mutual concessions seems to be the logical and desirable outcome of existing conditions. The meetings held at Toronto were characterized by the well digested contents of the papers presented and by the clearness of exposition shown by the authors. Much interest was given to these meetings also by the presence of a number of foreign guests and members of the societies.

On the afternoon of Wednesday, August 18th, the British Association for the Advancement of Science was welcomed to the Dominion of Canada, to the Province of Ontario, and to the City of Toronto, by the Governor-General, the mayor of the city, and other officials. In these ceremonies the intense patriotism of the jubilee year and the devotion of our British cousins to the work of their Association were alike pleasantly and prominently manifest. On the following evening Sir John Evans, President-elect of the meeting, read his address, printed in a recent issue of this JOURNAL, before a large and brilliant audience. The formal addresses of the Sectional Presidents were given during the forenoon of Thursday, after which the sections proceeded to the presentation and discussion of less formal communications. Daily or more frequent sessions were held by the various sections, and the meeting continued until August 25th. The well-planned excursions and social events con-

tributed greatly to the enjoyment and profit of all.

Delegates from the United States were present in large numbers and participated in the proceedings of this meeting of the British Association. Many of them were courteously invited to sit with the sectional committees and to join them in their deliberations. The formation of new and the renewal of old acquaintanceships, and the free interchange of thought thus afforded, made the meeting seem, to quote the language of the admirable address of Sir John Evans, like a 'family gathering in which our relatives, more or less distant in blood, but still intimately connected with us by lauguage, literature and habits of thought, have spontaneously arranged to take part.'

In its management of business details the British Association presents some instructive points of contrast with our own organization. Without entering here upon a discussion of these points, it may be useful to mention three wherein the British Association appears markedly superior to the American. The first of these is the absence, at the summer meetings, of repeated and prolonged sessions of the Council, or governing body. Secondly, no sessions affording opportunity for miscellaneous debate by members in general are held. The entire energy of the members in attendance may thus be turned toward the object of the Association—the advancement of science. Thirdly, there is the advantage which comes from the greater freedom and powers of the sectional committees. These virtually control the proceedings of their respective sections at any meeting, and the work of a section goes on with the vigor and effectiveness which characterize our independent or affiliated societies. In addition to these administrative matters, one cannot help noting the greater enthusiasm of our British kin for science and for scientific men, and the larger proportion of attendance at their meetings of their best men. With them the meeting of the British Association is one of the most important events of the year. With us, widely separated over a continent, there is less opportunity for the cultivation of enthusiasm and greater difficulty in coming together; but who shall say that these are insurmountable obstacles in the way of a worthy scientific zeal and enterprise?

INTERNATIONAL AMENITIES AT DETROIT AND TORONTO.

In accordance with action taken at Buffalo last year, members of the British Association for the Advancement of Science attending the meeting of the American Association at Detroit were made honorary members of the latter body for the 1897 meeting. Perhaps a score of British and Continental scientists availed themselves of this privilege; several of them took part in the work of the Sections, joining freely in discussion and in some cases participating also in the labors of the presiding officers; and it was a general opinion that the presence of these distinguished representatives of science from over seas contributed materially to the success of the Detroit meeting. Especially noteworthy, as an indication of the comity between the two Associations, was the presence of Professor A. B. Macallum, the Local Secretary of the British Association for the Toronto meeting, who came specially to extend in person the courtesies of this body and to make arrange-

ments for transportation, etc., on behalf of Americans desiring to visit Toronto. The Detroit meeting was unexpectedly successful; it is true that the attendance was barely 300 and therefore below the average, but in number and quality of papers, in value of discussions, and in attendance at sectional meetings it ranked, in the judgment of most of the old-time members present (including four past-Presidents), as one of the best meetings in the history of the Association. The pleasure of the meeting was enhanced by exceptional local interest, displayed not only by the local committee but by the citizens generally, and also by the notably excellent press of Detroit; but a large measure of the pleasure, as well as the success, of the meeting must be ascribed to the presence of so many prominent members of the British Association.

In the opinion of old-time members, the Toronto meeting of the British Association was well above the average in number and quality of communications and in the discussions, while the attendance (about 1360), though less than the average, was fully up to expectations. To this meeting American scientists, and particularly members of the American Association, contributed freely. This participation was encouraged by the older Association in making the general and sectional officers of the American Association honorary members, and in placing members of the American body on exactly the same footing as their own members, *i. e.*, admitting them to the privileges of the Association on payment of the customary membership fee. Some 250 American scientists, including about a score of officers of the American Association, availed themselves of these privileges; of these something less than 100 went directly from Detroit, leaving fully 150 Americans, nearly all members of the American Association, who chose Toronto rather than Detroit as a place for scientific association and discussion, thereby paying the highest possible compliment to the older organization. They were made welcome in the Sections and general meetings; many of them were placed on sectional committees (which are more important in the British body than in the American), and several of them were elected to vice-presidencies; they presented numerous formal communications, joined freely in discussion, aided in administration even to the extent of actually presiding in the absence of the sectional presidents, and contributed in due measure toward shaping the scientific character of the meeting. A noteworthy feature was the attention given in the Section of Geography to a series of papers prepared expressly for this meeting by representatives of our National Geographic Society. In the general meetings and public functions special attention was shown to the American Association collectively as well as to the individual members; the officers were invited to occupy platform seats, and at the closing banquet two representatives of the American body were among the rather limited number of speakers. At this banquet, as on other occasions, the members of the two Associations had the same footing; some officers of both were guests, the list including the general officers, Vice-Presidents, and past-Presidents of the American Association. In thus extending courtesies to the younger organization of similar aims, the British Association departed considerably from its traditions and its eminently conservative custom; and it cannot be doubted that the departure must be credited in the first place to the good offices of the local committee, and in the second place to the exceptionally large common membership, growing out of the fact that in Canada the fields of the two Associations overlap.

The near conjunction of the two meetings in time and place has undoubtedly been most beneficial; it has extended individual

acquaintance between investigators pursuing related lines of research; it has made each Association better acquainted with the character and purposes of the other; it has increased mutual esteem between the men and institutions; and it strengthened both bodies in attendance and in quality and quantity of work, and has been especially beneficial in diffusing knowledge of and interest in scientific matters among the people of two countries. Some of the benefits were felt at the meetings; yet it seems fair to regard these as but the germs of greater benefits to come as the personal and collective relations begun at Detroit and Toronto mature and strengthen.

It seems specially desirable to note the international amenities characterizing the Detroit and Toronto meetings, since minor misapprehensions have come to the surface. For example, it has been alleged in the newspapers that certain members of the American Association were treated with discourtesy at the Toronto meeting. It must be evident, in view of the prevailing harmony and the unprecedented warmth of the courtesies extended by each of the Associations, that the sources of individual criticism are to be found in personal matters and not at all in general feeling. It may not be amiss to add that the Local Secretary of the British Association has explained, through the public press, that certain Americans, who complained, through the medium of associated press despatches, of discourtesy at Toronto, were not registered as members of the British Association, and therefore occupied the precise footing of the general public, which, in the British Association, is not entitled to admission to the meetings or other participation in the work of the body. The great and significant fact is that the relations between the two Associations at Detroit and Toronto were most cordial, sympathetic and beneficial; this fact assuredly overshadows any and all petty misapprehensions, and must serve to render the meetings memorable.

W J McGee.

THE SPREAD OF LAND SPECIES BY THE AGENCY OF MAN; WITH ESPECIAL REFERENCE TO INSECTS.

Among the many influences which during the last century or two have been affecting that unstable condition of life which is expressed in the words 'the geographical distribution of animals and plants' none has approached in potency the agency of man exerted both purposely and unwittingly or accidentally.

Natural spread was for centuries the rule. Species dispersed under natural conditions along the line of least resistance. Winged animals and seeds were spread by flight and by the agency of winds, and at their stopping places thrived or did not thrive according as conditions were suitable or not suitable. Aquatic animals and plants and small land animals and plants were distributed by the action of rivers and streams and by the ocean itself. Wonderful migrations have occurred, commonly with birds, more rarely with other animials; ice floes and driftwood have carried animals and plants far from their original habitats and even volcanic action has taken part in the dispersal of species. Smaller animals, especially mollusks and insects, and the seeds of plants have been carried many hundreds of miles by birds and lesser distances by mammals.

With the improvement of commercial intercourse between nations by land and by sea another factor became more and more prominent, until in the present period of the world's history the agency of man in the spread of species, taking all plant and animal life into consideration, has become the predominating one. Potentially cosmopolitan forms, possibly even insular in-

digenes, have by this important agency become dispersed over nearly all of the civilized parts of the globe, while thousands of other species have been carried thousands of miles from their native homes, and have established themselves and flourished, often with a new vigor, in a new soil and with a novel environment.

It is obvious that this agency is readily separable into two divisions : *a*, intentional; *b*, accidental.

a. Intentional Importations. Since early times strange plants and animals have been carried home by travelers. Conquering armies have brought back with the spoils of conquest new and interesting creatures and useful and strange plants. With the discovery of America and with the era of circumnavigation of the globe such introductions into Europe of curious and useful species, plants in particular, increased many fold, while with the colonization of America and other new regions by Europeans there were many intentional return introductions of Old World species conducive to the welfare or pleasure of the colonists. Activity in this direction has been increasing and increasing. Public botanical gardens and many wealthy individuals in all quarters of the globe have hardly left a stone unturned in their efforts to introduce and acclimatize new plants, particularly those of economic importance and æsthetic quality, not failing occasionally, it must parenthetically be said, to establish some noxious weed, or some especially injurious insect; while it is safe to say that probably the majority of the desirable plants of Europe which will grow in the United States have already been introduced, and that there has been an almost corresponding degree of activity in the introduction of desirable plants from the United States into Europe. In all this host of valuable introductions there have been comparatively few which have turned out badly, aside from failures of establishment. The wild garlic (*Allium vineale*), that ubiquitous plant which gives its taste to milk, butter, and even to beef during the spring and summer months in many of our States, is said to have been intentionally introduced by the early residents of Germantown, Pennsylvania. The water hyacinth (*Piaropus crassipes*), originally grown for ornament in a pond near Palatka, Florida, escaped into the Saint John's river about 1890, and has multiplied to such an extent as to seriously retard navigation and to necessitate government investigation. The distribution of the orange hawk-weed (*Hieracium aurantiacum*), a dangerous species which has ruined hundreds of acres of pasture land in New York of recent years, was originally aided by a florist as a hardy ornamental plant. The European woad-waxen (*Genista tinctorium*) was early introduced at Salem, Mass., in fact about thirty years after the settlement of the colony. It has apparently not been used as a dye plant, but for garden and ornamental purposes only. During the last few years it has become a noxious weed throughout Essex and the adjoining counties. Standing on a rock at Swampscott on July 9th, last, the writer was able to see that the country for miles around was colored a bright yellow with enormous masses of this plant. Similar instances are fortunately rare and the majority of our noxious weeds have been accidental introductions.

Intentional introductions of animals, however, have by no means resulted as advantageously as intentional introductions of plants, with the exception of the truly domesticated species, such as the horse, ass, cow, sheep, pig, dog, cat, poultry, honey bee and silk worm of commerce. Even with such species, the grazing ranges of Australia have been overrun by wild horses to such an extent that paid hunters shoot them at a small sum per head, and the European rabbit has become a much worse plague on the same island continent.

Intentional introductions of wild species, however, have almost without exception resulted disastrously.

At various intervals between 1850 and 1867 a few pairs of English sparrows were introduced into our northeastern States to destroy canker worms, and to-day this species is an ubiquitous and unmitigated pest throughout all the austral and transition regions of North America, finding its limit only at the borders of the boreal zone, while the place of the injurious insect it was imported to destroy has been taken by another and worse insect pest which it will not touch.

In 1872 Mr. W. Bancroft Espeut imported four pairs of the Indian mongoos from Calcutta into Jamaica for the purpose of destroying the 'cane-piece rat.' Ten years later it was estimated that the saving to the colony through the work of this animal amounted to £100,000 annually. Then came a sudden change in the aspect of affairs. It was found that the mongoos destroyed all ground-nesting birds, and that the poultry as well as the insectivorous reptiles and batrachians of the island were being exterminated by it. Injurious insects increased in consequence a thousand fold; the temporary benefits of the introduction were speedily wiped away, and the mongoos became a pest. Domestic animals, including young pigs, kids, lambs, newly-dropped calves, puppies and kittens were destroyed by it, while it also ate ripe bananas, pine apples, young corn, avocado pears, sweet potatoes, cocoas, yams, peas, sugar cane, meat and salt provisions and fish. Now, we are told, nature has made another effort to restore the balance. With the increase of insects due to the destruction by the mongooses of their destroyers has come an increase of ticks which are destroying the mongoos and all Jamaicans rejoice.

The flying foxes of Australia (*Pteropus* sp.) are animals which are very destructive to fruit in their native home. Frequently some well-meaning but misguided person will arrive on a steamer at San Francisco with one or more of those creatures as pets. While it is not probable that any of the flying foxes will thrive in northern California or in fact in Austral regions, the experience is too dangerous a one to try, and the quarantine officer of the California State Board of Horticulture has always destroyed such assisted immigrants without mercy.

Less than thirty years ago (in 1868 or 1869) Professor Trouvelot imported the eggs of the gypsy moth (*Porthetria dispar*) into Massachusetts. The insect escaped from confinement, increased in numbers, slowly at first, more rapidly afterwards, until in 1889 it attracted more than local attention, with the result that in 1890 the State began remedial work. This work has steadily progressed since that time and the State has already expended something over a half million of dollars in the effort to exterminate the insect, and it is estimated that one million five hundred and seventy-five thousand dollars more must be used before extermination can be effected.

Contrast with this a single intentional importation which has had beneficial results. The Australian ladybird (*Vedalia cardinalis*) was introduced into California in 1889 with the result of saving the whole citrus growing industry of the State from approaching extinction through the ravages of the cottony-cushion scale (*Icerya purchasi*). Later importations of the same insect into South Africa and Egypt also resulted beneficially.

We have thus had sufficient experience with intentional importations to enable us to conclude that while they may often be beneficial in a high degree they form a very dangerous class of experiments and should never be undertaken without the fullest understanding of the life history and

habits of the species. Even then there may be danger, as with a new environment habits frequently change in a marked degree.

b. Accidental introductions. The agency of man, however, has been more potent in extending the range of species and in changing the character of the faunas and floras of the regions which he inhabits by means of accidental importations.

The era of accidental importations began with the beginning of commerce and has grown with the growth of commerce. The vast extensions of international trade of recent years, every improvement in rapidity of travel and in safety of carriage of goods of all kinds, have increased the opportunities of accidental introductions, until at the present time there is hardly a civilized country which has not, firmly established and flourishing within its territory, hundreds of species of animals and plants of foreign origin, the time and means of introduction of many of which cannot be exactly traced, while of others even the original home cannot be ascertained, so widespread has their distribution become.

These accidental importations would at first glance seem to have been more abundant with plants than with animals, since the opportunities for the carriage of seed, especially flying or burr-like seed, and especially when we consider the vitality of this form of the plant organism, are plainly manifold, but I shall later show that possibly even this obvious generalization must be modified in view of the multitudinous chances for free travel which the smaller insects have under our modern systems of transportation.

The agencies which have mainly been instrumental in the accidental distribution of plants are:

1. Wind storms. It is obvious that light flying seeds may be carried many hundreds of miles by hurricanes and may fall in new regions.

2. Water. This is a very important agency in the distribution of plants upon the same continent, but less important as affecting intracontinental distribution. Still they may be carried by this means from one island to another adjoining island, and when lodged in the crevices of the driftwood they undoubtedly travel greater distances.

3. Birds. Seeds are frequently carried great distances by birds. Many of the larger seeds will germinate after passing through the alimentary canal of a bird, and may thus be eaten at one point and voided with the excrement at a widely distant point. It has been shown, for example, that the local distribution of *Rhus toxicodendron* is greatly affected by the carriage and distribution of the seed in this way by the common crow. Smaller seeds are carried in earth on the feet of birds. Darwin's example of a wounded red-legged partridge which had adhering to its leg a ball of earth weighing $6\frac{1}{2}$ ounces, from which he raised 32 plants of about five distinct species, is an evidence of the possibilities of this agency, while his experiment with $6\frac{3}{4}$ ounces of mud from the edge of a pond which produced 537 distinct plants, an average of a seed for every 6 grains of mud, is still more conclusive.

4. Ballast. This is the first of the distribution methods which may be combined under the head of 'agency of man.' The discharge of earth ballast by vessels coming from abroad has been a notable means of distribution of plants by seed. We have just seen how many seeds may germinate from a very small lump of earth, and the possibilities in this direction of the many thousands of pounds of discharged ballast are very great. In fact the ballast grounds in the neighborhood of great cities are invariably favorite botanical collecting spots; they have usually a distinctive flora of their own, and from these centers many introduced plants spread into the surrounding country.

5. Impure seed. The great industry in the sale of seed which has grown up of late years is responsible for the spread of many plant species, principally, it must be said, undesirable species. Mr. L. H. Dewey says: "It may be safely asserted that more of our foreign weeds have come to us through impure field and garden seeds than by all other means combined."

6. The packing material of merchandise. The hay or straw used in packing crockery, glassware or other fragile merchandise is a frequent carrier of foreign seeds. Such goods frequently reach the retailer without repacking, and the hay or straw is thrown out upon the fields or used as bedding for domestic animals and carried out with the manure.

7. Nursery stock. Plants are often accidentally introduced by means of seeds, bulbs and root stocks attached to nursery stock or among the pellets of earth about the roots of nursery stock. The extraordinary development, of late years, of commerce in nursery stock has undoubtedly been responsible for the intracontinental carriage of many species of plants in this way.

Instances of the accidental spread of larger animals by man's agency are necessarily wanting. Of the smaller mammals the house rat and the house mouse have been accidentally carried in vessels to all parts of the world and have escaped and established themselves, the former practically everywhere except in boreal regions, or only in its southern borders, and the latter even as far north as the Pribyloff Islands, as I am informed by Dr. Merriam. Small reptiles and batrachians are often accidentally carried by commerce from one country to another, but although there are probably instances of establishment of such species none are known to me at the time of writing.

Land shells are often transported accidentally across the ocean in any one of the many ways in which the accidental transportation of plants and insects may be brought about, and by virtue of their remarkable power of lying dormant for many months are able to survive the longest journeys. The conditions which govern the establishment of species in this group, however, seem somewhat restrictive, whence it follows that comparatively few forms have become widespread through man's agency, although Binney mentions a number of European species which have been brought by commerce into the United States and have established themselves here, mainly in the vicinity of the seaport towns of the Atlantic coast.

With the earthworms a striking situation exists. It has been shown that, "without a single exception, the Lumbricidæ from extra-European regions are identical with those of Europe; there is not a variety known which is characteristic of a foreign country."* Careful consideration of the evidence seems to show that this is due to accidental transportation by the agency of man.

Comparatively little has been done in the study of the geographical distribution of insects. In the words of Wallace:

"The families and genera of insects are so immensely numerous, probably exceeding fiftyfold those of all other land animals, that for this cause alone it would be impossible to enter fully into their distribution. It is also quite unnecessary, because many of the groups are so liable to be transported by accidental causes that they afford no useful information for our subject, while others are so obscure and uninteresting that they have been very partially collected and studied, and are for this reason equally ineligible."

Nevertheless, the time has already arrived with some groups, and is not far distant

*F. E. Beddard, Text Book of Zoogeography, Cambridge, 1895, p. 153.

even with the others which Mr. Wallace has termed 'obscure and uninteresting,' when, owing to the indefatigable industry of entomologists as a class, important facts can be gained along distribution lines from the group of insects. Thus it is only within the past few months that the publication of Mr. W. F. Kirby's 'Catalogue of the Odonata of the World' has made it possible for Mr. G. H. Carpenter, of the Royal Dublin Society, to prepare a comprehensive paper on the geographical distribution of the dragon-flies, a group in which a comparatively few workers have interested themselves. It is in a measure true to-day, as it was entirely true when Wallace wrote, that "many of the groups are so liable to be transported by accidental causes that they afford no useful information for our subject," yet even with the group in which the greatest obscurity as to the original home of the species has existed, owing to a very easy and most frequent commercial transportation—the Coccidæ or scale-insects—the continued discovery and characterization of new forms from all parts of the world, and especially of those existing in wild regions, away from the influence of man, are gradually giving us an insight into the probable character of the original coccid faunas of more or less restricted regions.

By reason of the drawbacks mentioned, Wallace considered only "a few of the largest and most conspicuous families which have been so assiduously collected in every part of the globe and so carefully studied at home as to afford valuable materials for comparison with the vertebrate groups." These groups included 16 families of diurnal Lepidoptera and six of the families of Coleoptera. Even with this restriction among the beetles, however, he must have had some difficulties with the accidental importations, for among the beetles are hundreds of examples of this class of introductions. For example, writing later in his Island Life, the great naturalist shows that in 1880 the total number of species of beetles known in the Azores amounted to 212, of which 175 were European. Out of these, however, no less than 101 were believed to have been introduced by human agency. Concerning St. Helena he quotes Mr. Wollaston's opinion that 74 of the 203 species have certainly been introduced by the agency of man.

In considering the question as to the regions with which an interchange of forms is most likely to occur, it is obvious that they are those which have the greatest similarity of climate, and, most nearly, identity in point of time of seasons, those in fact which are most likely to afford similar environmental conditions. A study of the similarity of faunas and floras already existing will lead us to the same result. Wallace has pointed out that with the Coleoptera the best marked affinities between regions are those between the Nearctic and the Palearctic, the Oriental and Australian, the Australian and the Neotropical, all of which appear to be about equal in each case. Next comes that between the Ethiopian and the Australian on the one hand and the Ethiopian and the Neotropical on the other, which also appear about equal. Then follows that between the Nearctic and Neotropical regions, and lastly, and by far the least marked, that between the north temperate and south temperate regions.

Further, in the consideration of accidental commercial importations, the amount and frequency of commercial interchange and the rapidity of the journey are most important factors.

From all of these considerations combined we arrive at the conclusion that the regions with which accidental interchange of species should be most frequent are Europe and North America, and this is with insects to a certain extent borne out

by the facts. The introduction of species from Europe into North America is of every-day occurrence and their establishment is far from rare. The carriage of American species to Europe is an equally frequent matter, but their establishment is much less frequent.

I have studied in this connection—my profession being that of an economic entomologist—principally the species which are prominent as injurious to horticulture or agriculture or in other ways inimical to man. Listing the insects of prime economic importance in the United States, the species each of which almost annually causes a loss of hundreds of thousands of dollars, we find that they number seventy-three. Of these thirty are native, while thirty-seven species have been introduced, six species being of doubtful origin. Of the thirty-seven introduced species, thirty have come to us from Europe, all, with one exception, as accidental importations.

Of the prominent European injurious insects, on the other hand, but three are said to have come from America; the grape-vine Phylloxera (*Phylloxera vastatrix*), the woolly root-louse of the apple or 'American blight' (*Schizoneura lanigera*), and the Mediterranean flour moth (*Ephestia kuhniella*). Of these but one is certainly American—the Phylloxera. The origin of the Schizoneura is somewhat doubtful, while the Mediterranean flour moth is not American, but probably came to us from Europe, although originally it is probably Oriental.

As with these insects of prime economic importance, so it is with other less noted species. There have been rather frequent establishments of European species in America, but practically none of American species in Europe. The reason for this curious condition of affairs is difficult to find. The general trend of accidental importations seems to have been westward, and it is doubtless a fact that certain of our now cosmopolitan forms were originally Asiatic and have traveled westward, through Europe, to and across America, and thence to Hawaii, New Zealand and Australia. The existence of such a law is borne out in the study of plants as well. The statement just made regarding insects of prime economic importance is almost exactly paralleled with the plants classed as weeds. It has thus been shown that, out of two hundred American weeds, one hundred and three are introduced, of which ninety-six are from Palearctic regions, sixty-eight being native to Europe, while it seems that less than half a dozen American species have become troublesome in Europe. A number of American species, however, have been carried to Australia and flourish there with vigor.

This general trend from east to west has always been in the direction of the newer civilization—from the older civilization to the newer. That this in itself is significant cannot be doubted, and in the case of the insect and plant enemies of agriculture the facts surrounding this condition are almost in themselves sufficient to account for this directive movement. I have shown in another paper that the denser population of the older countries and the resulting vastly smaller holdings in farms, the necessarily greatly diversified crops, the frequent rotations of crops, together with the clean and close cultivation necessitated by the small size of the holdings, and the cheaper and more abundant labor, will all operate as a barrier against the establishment of injurious species, while the reversed conditions in a newer country at once liberate an introduced species from the repressive conditions which affected it in its original home and encouraged its establishment, multiplication and spread. But there are deeper causes than this at work. It has been suggested that the flora and fauna of America, the older continent, have

become degenerate through age and cannot successfully resist competition with the more vigorous forms introduced from the younger continent of Europe,* and that there are not-yet-formulated climatic differences favorable to the development of Palearctic forms on the American continent; but these theories seem insusceptible of proof, and for the present we must content ourselves to accept the facts as we find them.

The insects which are accidentally imported are carried in three main ways. Either (1) they are unnoticed or ignored passengers on or in their natural food, which is itself a subject of importation, such as nursery stock, plants, fresh or dried fruit, dried food stuffs, cloths, lumber or domestic animals; or (2) their food being the packing substances used to surround merchandise or the wood from which cases are made, they are thus brought over; or (3) they may be still more accidental passengers, having entered a vessel being loaded during the summer season, and hidden themselves away in some crevice. The coleopterists (Hamilton and Fauvel) make a distinction by name among these classes, calling the first group 'insects of commerce' and the latter 'accidental importations.'

It would appear on the face that these more strictly accidental importations must be rarer than those which are termed commercial importations, yet of the 156 introduced Coleoptera recorded by Dr. Hamilton in 1889, sixty only were considered by that writer as insects of commerce, while 96 he thought had been brought over in this accidental way.

The remaining Coleoptera common to North America and the Palearctic region, 278 in all, Dr. Hamilton considers to be practically circumpolar species, or at least not imported. Fauvel in his remarks and additions to Hamilton's catalogue raises the number of non-introduced or circumpolar species to 366, leaving 125 as imported, of which only 28 appear to have been imported from temperate Europe, the rest being cosmopolites or subcosmopolites. Of the latter class he thinks that 59 originally came from the temperate Europeo-Siberian fauna, 10 from the Oriental fauna, 15 from the Ethiopian, 4 from the Neotropical, 7 being uncertain and 2 unknown.*

It should be noted, however, that there is grave room for difference of opinion regarding a number of the European species considered by him as indigenous to North America. *Scolytus rugulosus*, *Hylastinus trifolii*, *Anthrenus scrophulariæ*, *Sitones hispidulus*, *Cryptorhynchus lapathi*, and a number of others which might be specified, have undoubtedly been imported from Europe and were quite possibly originally imported.

There are obstacles in the way of the establishment and spread of species which are imported quite by accident which usually do not exist in the case of the so-called commercial importations. In many cases, entering the vessel by accident, they exist there as single individuals, and upon liberation, even should the conditions be favorable, only gravid females could perpetuate the species. Then also the majority of such specimens are liberated, upon the unloading of the vessel, upon the wharves. The water front of a seaport city is not a favorable place for the establishment of a species which feeds on living vegetation. Frequently, even when it is a species well fitted for acclimatization, it will have to fly or be carried for miles inland before it can find a place possible for the establishment of the species. So it happens that while foreign insects are frequently found in living condition about the wharves of our

* The spread of European species in Australia has been explained by the superior energy of the younger races of the Palearctic region.

* Hamilton, in his 1894 paper, raises the number of Coleoptera common to the two countries to 594, making the number of introduced species 216.

larger seaports during the summer months, almost none have succeeded in getting a foothold in the vicinity. Mr. Otto Lugger, when living in Baltimore, Md., made a collection of many species of foreign insects found upon the wharves, yet he has recorded the establishment of but a single species, viz, *Aphodius erraticus*, an European dung-beetle, which managed to get to Druid Hill Park, where it bred in the dung of the tame deer, afterwards spreading into the surrounding country and breeding in the dung of sheep and other domestic animals.

Practically, therefore, after many years of the most active commerce, the insect faunas of the immediate vicinity of the larger seaports, like New York, Boston, Philadelphia and Baltimore, have not been greatly changed by the introduction of foreign elements.

All of the household insects and true city insects are, of course, exceptions, to this conclusion and the strong flying, vigorous, and simple living dipterous insects—the very ones most likely to enter a loading vessel and to escape on the discharge of its cargo—will many of them find proper places for breeding. It is likely that a much larger proportion of the many species of Diptera common to Europe and North America have been brought over in this accidental manner than is the case with the Coleoptera.

But often these purely accidental species are carried inland in packing cases, into the cracks of which they may have crawled, or even in the trunks of passengers, and they may then be liberated in more favorable localities. For example, Mrs. H. G. Hubbard, after spending the summer on Prince Edward's Island, returned in the autumn to Detroit, Mich., and in unpacking her trunks her husband found two specimens of *Phytonomus punctatus*, a species not previously known to occur in Michigan, although found there in injurious numbers a year or so later. It is altogether likely that the imported elm leaf-beetle (*Galerucella luteola*), an insect which enters houses for hibernating purposes, was first brought to America in this manner.

It is, however, the accidental commercial importations which theoretically stand the best chance of establishing themselves, since, in the first place, they are generally imported in or upon their natural food. In the second place, they generally occur in considerable numbers, instead of as isolated individuals, as with the more purely accidental importations; and, in the third place, they are usually carried as originally packed, far from the port of entry.

With insects brought over on plants or nursery stock the conditions could not well be much more favorable. Their supply of food is looked after with care, the host plant is soon put in the ground in the best of surroundings, and the greatest care is taken of the choice importation. Upon or in importations of this kind are carried Coccidæ in all stages of growth, and often, fortunately, their enclosed parasites, the eggs of Aphididæ, the larvæ of wood-boring Coleoptera, the eggs of many other insects, the cocoons of small Lepidoptera, and probably even in rare cases the larvæ of Lepidoptera, since it now seems likely that *Euproctis chrysorrhœa* was imported into Massachusetts on nursery stock in its larval hibernacula. The Coccidæ, however, are most abundantly carried in this way. Under natural conditions these insects have usually a rather restricted distribution, but by means of this commercial distribution many of them have become of almost world-wide range, and the end will certainly not be reached until every country possesses every species of scale insect which can possibly live in its climate. A few instances drawn from a recent paper by Mr. Cockerell will illustrate this fact:

Diaspis amygdali, or *lanatus*, was described from Australia in 1889. To-day we know it

from Australia, Ceylon, Hong Kong, Japan, several localities in the United States, Jamaica, San Domingo, Grand Cayman, Barbadoes, Martinique, Trinidad and Cape Colony.

Aulacaspis rosæ was described from Europe, but is now found also in the United States, Australia, New Zealand, the Sandwich Islands, China and Jamaica.

Chionaspis citri was described from Louisiana and Cuba in 1883 and is now known from Trinidad, Antigua, Demarara, Bermuda, Mexico, Tonga, New Zealand and Australia.

Howardia biclavis was described in 1883 from specimens on hothouse plants in Washington, D. C. Now it is known out-of-doors from Trinidad, Mexico, Tahiti, Sandwich Islands and Ceylon.

Lecanium oleæ is found in Europe, the United States, the West Indies, Mexico, Sandwich Islands, New Zealand, Australia and Cape Colony.

The hymenopterous parasites of the Coccidæ, by virtue of their mode of life, have spread almost equally with their hosts by means of this commercial transportation. I have been able to show recently that by this means a number of species of the Chalcidid subfamilies Aphelininæ and Encyrtinæ have, in comparatively recent years, become cosmopolites. For example:

Aspidiotiphagus citrinus, originally described from California in 1891, is now found in many other portions of the United States, in the West Indies, Italy, Austria Ceylon, China, Formosa, Japan, Cape Colony, Queensland, South Australia and Hawaii. Practically the same remarkable distribution is followed by *Prospalta aurantii*, *Aphelinus mytilaspidis*, *A. diaspidis* and *A. fuscipennis*, while the remarkable and system-breaking Encyrtine—*Arrhenophagus chionaspidis*, described by Aurivillius from Swedish specimens in 1888, has since been found in Austria, Italy, several portions of the United States, Ceylon, Japan, Formosa and China.

Only second to the Coccidæ in the facility with which they are transported in this way are the Aphididæ. These insects, however, are fragile, soft-bodied and unprotected. They are readily carried, however, in the winter-egg condition and many species are rapidly becoming cosmopolitan. They have not been studied, however, elsewhere than in Europe and the United States, and the extent to which this commercial distribution has been carried can only be surmised. A suggestion of this extent, however, occurred to me when within the past few weeks specimens of *Aphelinus mali*, a common parasite of Aphididæ in Europe and North America, were received from such a comparatively out-of-the-way corner of the world as Passarœan, Java.

Other still smaller and still less studied insects are undoubtedly carried by this method of transportation, as the recently discovered identity of certain North American Thysanopterâ with those of Sweden and Russia would seem to show. The small plant-feeding mites of the family Phytoptidæ are particularly subject to this form of commercial distribution, and when they are fully studied, it will doubtless be found that many forms have become subcosmopolitan.

Of larger insects, nearly all of the wood-boring beetles common to Europe and the United States have probably been brought over in this way. *Zeuzera pyrina*, the large wood-boring cossid moth, also probably came over on living plants; and, as I have just stated, the newly imported brown-tail moth, *Euproctis chrysorrhœa*, was probably at Boston with nursery stock.

Careful observations on the insects transported with this class of merchandise have never been made, except, possibly, at the port of San Francisco. At this port the

State Board of Horticulture has established, under State laws, a quarantine for all incoming plants and fruit. The entomologist and quarantine officer, Mr. Alexander Craw, has entire jurisdiction over such articles consigned to points within the State, and examines, destroys and fumigates at his discretion. He has not, however, in his reports, given us complete lists of the insects collected in this work, although I understand, from persons who have visited his office, that he has preserved collections of the more important species from an economic standpoint. The vessels examined have, almost without exception, come from Pacific ports, and the difficulty of naming insect material thus received would be very great. It is this fact which has probably hitherto prevented the publication of a general list. A list of the scale insects, however, has been published.*

Between July 2, 1894, and August 29, 1896, Mr. Crew inspected 232 vessels carrying plants or other articles liable to be infested with living insects, and consigned to California individuals or firms. 122 lots he found clean and passed; 40 lots he admitted after fumigation; 20 lots he destroyed and 78 lots he destroyed in part. One lot, consisting of 1,000 boxes of apples, he sent back on the refusal of the owner to allow them to be fumigated.

Living plants and nursery stock afford, then, perhaps, the most certain means for the accidental transmission and subsequent establishment of many kinds of insects. Commerce in objects of this class is rapidly increasing and has already assumed considerable proportions, the imports into the United States alone in the fiscal year ending June 30, 1896, having reached a value of nearly $1,000,000, while the previous year they amounted to something over $600,000.

* Bull. 4. Tech. Ser. Div. Entom. U. S. Dept. Agric., 1896, pp. 40–41.

No great elaboration will be needed concerning the importation of foreign insects upon fruits, fresh and dry; other dry food stuffs; cloths; lumber, or domestic animals. Fruits were imported into the United States in the fiscal year 1895–6 to the value of nearly $20,000,000, and, unquestionably, upon imported fruits are carried many insects. The opportunities for the establishment of species coming with fresh fruit, however, are obviously slight as compared with those which come on living plants or in dried food-stuffs, and, as a matter of fact, it appears that already nearly all of the dried-food insects have become cosmopolitan. The same may be said of the insects which affect domestic animals. The forms which are truly parasitic in the larval stage have most of them been carried everywhere, while the other forms which attack domestic animals only as adults have some of them been carried far and wide. As an example, we may recall the European *Hœmatobia serrata*, which was brought to New Jersey probably in 1886, and which has spread over the entire country from Maine to California.

The fact that insects may be, and doubtless are, transmitted in the material used in packing heavy or delicate merchandise must not be overlooked. We have already shown that dangerous weeds have been transmitted in this way, and when the material is hay or straw the danger of importing certain injurious insects becomes great. *Cecidomyia destructor*, the well-known Hessian fly, is supposed to have first been brought to the United States from Europe in straw bedding on troop vessels during the War of the Revolution, and to have recently been carried from Europe to New Zealand in the straw packing of merchandise. Laws recently proposed in New Zealand, Australia and Cape Colony provide that such straw or hay packing shall be burned immediately the case is opened.

Dr. H. Loew, in his well known paper, 'Ueber die Diptern-fauna des Bernsteins,' has shown that several of the species of the genera *Oscinis* and *Chlorops* have gained a wide distribution through commerce, and this probably happened through their occurrence in hay or straw used as packing, since they live in the stems of grains and grasses. Dr. Loew, by the way, considered the Diptera, by virtue of the simple conditions required for their existence, to be peculiarly susceptible to commercial and accidental distribution, and was inclined to believe that the majority of the many species common to Europe and North America have been imported into the latter country. He understood, however, the existence of a circumpolar fauna and wrote wisely and learnedly about the common ancestry of what he called analogous species. Whatever may be the cause, the Diptera seem fitted in the individual to withstand widely differing environmental conditions. The group, as a whole, has apparently little faunistic value either along broad lines or in a more restricted way. There are comparatively fewer characteristic genera in the main faunal regions of the world than in other groups of animals, and in our own country there are comparatively few species of restricted distribution. Very many individual species range through the Lower and Upper Austral, through the Transition and into the Boreal regions.

Aside from the Diptera, grains and grasses all over the world are subject to the attacks of a host of insects of all kinds, many of which hibernate on or within the stems, so that the proposed legal provisions of the English colonies mentioned are by no means unwise. The substitution of the wood material known as 'excelsior,' the use of which is becoming so common in this country, or of some other packing material, will shortly do away with a large share of this danger.

There are, of course, other less important methods by which insects may be transported, such as in earth or damp moss about the roots of plants and in sand used for ballast. These methods, however, are not very important as a rule, although it is stated that the destructive chigoe (*Sarcopsylla penetrans*) was carried in ballast in 1872, on a vessel from Rio Janeiro to the coast of Guinea, where it has established itself most perfectly, having been found 200 miles inland by Stanley.*

There remains one more source of accidental introductions and it is one which has been reasonably prolific as regards insects on several occasions. I refer to international expositions, which are now becoming of almost annual occurrence. At the Centennial Exposition at Philadelphia, in 1876, the insects occurring in the exhibits, especially of foreign grains, received some study by Dr. Riley, who published a short note in the Proceedings of the St. Louis Academy of Science for October 2, 1876. A special committee of the Philadelphia Academy, consisting of Drs. Horn, Leidy and Le Conte also prepared and published a report at this time, but none but well known and cosmopolitan forms were found. I am not familiar with the results of any studies of a similar nature made at the Paris Exposition Universelle of 1889, but have seen the title of a paper by M. Decaux which reads 'Etudes sur les insectes nuisibles receuillis à l'Exposition Universelle,' Paris, 1890, which, however, I have not been able to consult.

In 1893, however, careful observations were made at the World's Fair at Chicago by Mr. F. H. Chittenden, the results of which were published by Dr. Riley in Volume VI. of Insect Life. Insects to the number of 101 species were found in grain and other stored vegetable products. Seven species were found affecting animal products

* 'Die Umschau,' July 17, 1897, p. 523.

and 13 wood-feeding species were found in the forestry building. The interesting and significant fact is mentioned in this article that there was an exchange of seed samples between the representatives of different countries, which would, of course, greatly facilitate the spread of seed-inhabiting insects, and it was further shown that thousands of samples were taken away from open bags by visitors from all parts of this country and probably from other parts of the world. Moreover, at the close of the Exposition the sheaves of cereals used in the decorations were taken away by armfuls by visitors. After summarizing the habits and countries of origin of the different species, however, Dr. Riley expressed the opinion that no dangerous importations were made at this time. It seems altogether likely, however, that *Phyllotreta armoraciæ*, a European species which has established itself in northern Illinois, Iowa and Wisconsin since 1893, and which was found by Mr. Chittenden in that year in vacant lots near the exposition grounds, was an exposition importation. Moreover, an interesting Calandrid of the genus *Tranes*, the species of which are all Australian, has established itself injuriously in greenhouses in St. Louis as the result of the introduction of two plants of *Zamia spiralis* which were bought at the World's Fair. With these instances in mind we cannot but admit that other species heretofore overlooked probably escaped and have become acclimatized as the result of this exposition, and that such occasions, occurring as they do more and more frequently and drawing constantly increasing material from all parts of the world, will, unless precautionary measures are instituted, afford more and more frequent opportunities of a very favorable kind for the spread of injurious species.*

We have thus seen how great the opportunities are under our modern conditions for the transportation, in proper condition for establishment, of insects of many groups, and from this point of view it seems strange, in view of the very numerous importations, that more species do not become acclimatized even in North America, where, perhaps, we reach the greatest possibilities in this direction. Our most intimate commercial relations are with the great faunal region most like our own, and these relations are rapidly growing both with Europe on the east and with Asia on the west, although our Asiatic importations are more abundant from the Oriental region than the Palearctic, and from the Oriental we are not so likely to receive species which will acclimatize themselves. We have already pointed out that the faunistic relations with the Coleoptera (and undoubtedly with other groups) are least marked between the north temperature and south temperate regions, and this distinction is never likely to be disturbed by imported species on account of the diametrically opposed seasons. A species starting from Argentina in the height of summer will reach the United States in the dead of winter at a time least likely to favor its acclimatization. This point was first suggested by my colleague, Mr. E. A. Schwarz, in his paper entitled 'The Coleoptera common to North America and other Countries' (Proc. Entom. Soc. Wash. I., 182–194).

It appears from what we have shown that very many species are constantly being imported which do not become acclimatized. Many of the European species which we should most expect to take hold in this country have not done so, while

* During the later months of the World's Fair precautionary measures were instituted under Mr. Chittenden's supervision. Much dry food material was fumigated with bisulphide of carbon, and many samples which were very badly infected were burned. At least four new and dangerous species of insects were destroyed in this way.

with others it is the unexpected which has happened. As Osten Sacken says, speaking of the Diptera: "Importation will not occur for centuries in cases where it might be expected from day to day; and, again, it will sometimes take place under circumstances most improbable, and, *a priori* impossible to foresee." (Proc. Entom. Soc. Lond., 1894, p. 489.)

Why should the well-known *Pieris rapæ* have made its appearance in this country and spread far and wide, while the equally common and injurious *Pieris brassicæ* and *P. napi* have never been found here? Why should *Phytonomus punctatus* have flourished with us when it is hardly known as a clover enemy in Europe, and when the congeneric *Phytonomus meles* of Europe has never been found here? Why should *Coleophora laricella* have established itself here, and none of the other European Coleophoras (some of them of much greater distribution and hibernating in cases of protective coloration and shape, and attached to plants) have acclimated themselves amongst us? Why should *Calliphora vomitoria*, *Crytoneura stabulans* and *Stomoxys calcitrans* have been brought over at an early date and flourished to excess in America and many other countries, while *Sarcophaga carnaria* is unknown in any of them?

Mr. Schwarz has phrased it: "We stand here before some great unknown factor, viz, the individual character and inmost nature of the species which governs the introduction or non-introduction of each species—a factor which is variable according to each species * * *." But there is is no reason why a mystery need be made of this condition. In a word, it is the capacity of the individual species to accommodate itself to a more or less novel environment. Nowhere in the whole animal kingdom do we find the natural environment more complicated than with insects. Conditions are frequently dependent upon conditions in an almost endless chain. The phenomena of fatal parasitism are of vital importance as determining the abundance of the species and are curiously complicated. I have recently proved the existence of several fatal tertiary parasites and the probable existence of quaternary parasites with *Orgyia leucostigma* in Washington. Upon the condition of this chain of interdependencies rests the welfare of the primary host. If adverse conditions affect the quaternary parasite, the primary host suffers, for the tertiary parasites increase and kill off the secondary parasites, allowing an increase of the primary parasites which kill off the Orgyia. The famous instance of Darwin in which he showed that in a measure cats are responsible for the production of clover seed in England through the interrelations of cats, field mice and bumble-bees, is paralleled and outdone again and again among insects. Further, in no group of animals are the characteristics termed special protective resemblance and special aggressive resemblance, to say nothing of protective and aggressive mimicry, so well marked and so important in the life of the species as with the insects. *It is upon the degree of simplicity of its life—the degree of simplicity of its normal environment as a whole—that the capacity of a species for transportation and acclimatization, even into a parallel life zone, depends.*

Nevertheless, I am fully convinced that very many more species will stand transportation from the Palearctic to the Nearctic, from the Australian to the Oriental and the Neotropical regions, than would be supposed from a consideration of these points and from a knowledge of the comparatively few forms which have as yet been transported and acclimatized. Aside from the forms brought in with their food and thus under the most favorable conditions for establishment, it is only by a lucky chance with the average accidental

insect immigrant that it finds conditions for reproduction—a chance which may not occur once in very many times. Osten Sacken has pointed out that *Eristalis tenax* must have been brought here many times during four hundred years before it succeeded in establishing itself. Undoubtedly many of these immigrants die upon our wharves when a lucky chance like crawling upon the clothes of a person and thus being carried out into the country might have resulted in the establishment of the species. Given the *most favorable conditions* and many species will be able not only to accommodate themselves to a new environment, but certain of them will thrive better in the new than in the old. The effort to transport beneficial species from the Australian region and acclimatize them in the Nearctic region seemed a rash and unprofitable experiment on its face, and I confess that I for one had little hope of its success, yet it was successful with several species and transcendently successful with one.

Much has been written of late about the success of the work in the introduction of beneficial insects by Mr. Albert Koebele into Hawaii, under the auspices of the Hawaiian government. Some of the introductions seem, without doubt, to have been strikingly successful. Mr. R. E. C. Perkins has reported at some length upon this success and, in commenting upon its reasons, says:

"It becomes natural to ask why the success of the imported beneficial insects has been so pronounced here, while in other countries it has been attained in a comparatively small measure. The reason, I think, is sufficiently obvious. The same causes which have led to the rapid spread and excessive multiplication of injurious introductions have operated equally on the beneficial ones that prey upon them. The remote position of the islands, and the consequently limited fauna, giving free scope for increase to new arrivals, the general absence of creatures injurious to the introduced beneficial species, and the equability of the climate, allowing of almost continual breeding, may well afford results which could hardly be attained elsewhere on the globe. The keen struggle for existence of continental lands is comparatively non-existent, and, so far as it exists, is rather brought about by the introduced fauna than by the native one."

Mr. Perkins' reasons are all good, but he has not mentioned one prime reason of success, and that is that the most successful of the imported species have come from another portion of the same great faunal region, while others have been received from the region most closely allied, viz, the Oriental.

Wallace took the view that the effectual migration of insects is, perhaps, more than with any other class of animals, limited by organic and physical conditions. "The vegetation," he says, "the soil, the temperature, and the supply of moisture, must all be suited to their habits and economy; while they require an immunity from enemies of various kinds, which immigrants to a new country seldom obtain."

There is much truth in this statement, but it must be remarked that, in practical experience, immunity from enemies of various kinds is what insect immigrants find, not what they leave behind them. It takes some time before they weave a new chain of organism preying upon organism. Our insect importations from abroad when they are of economic importance, and those from Europe are very likely to be of such importance, leave their old insect enemies behind them and frequently are not readily attacked by native ones. These last accommodate themselves to the new comer in time, but for a while he enjoys comparative immunity. The rapid multiplication and spread of *Pieris rapæ*, of *Hæmatobia serrata*

of *Phytonomus punctatus*, of *Porthetria dispar*, of *Anthonomus grandis*, of *Icerya purchasi* and many others may probably be principally laid to this cause.

I should be remiss did I not refer to another aspect of the accidental introduction of species, viz, that it not only adds species to a native fauna, but also that it often causes the disappearance of native forms. Since the establishment, within our boundaries, of *Pieris rapæ*, our native *Pontia oleracea* has almost entirely disappeared in localities in which it formerly abounded, and in some sections has entirely disappeared. Since *Doryphora 10-lineata* came east and multiplied upon the cultivated potato in such prodigions numbers, the formerly common eastern *Doryphora juncta* has become a rare species. Walsh pointed out 30 years ago that one effect of the westward spread of the European *Mytilaspis pomorum* was to cause the gradual local disappearance of the native *Chionaspis furfurus*. Hubbard has shown that the increase of the imported *Mytilaspis citricola* in Florida was followed by the decrease of *Mytilaspis gloverii*, which, though not native, was an earlier importation—a most interesting, and, so far as records go, unique case. Instances might be multiplied which will show that the establishment of foreign species thus often produces at least a dual effect on the character of the fauna as a whole.

In closing, it will not be inappropriate to point out that the accidental importation of species is only one of the ways in which the agency of man is altering the character of native faunas, and that, in spite of its extent, it is really the least of the ways. The influence of civilization is immediately destructive to natural floras and faunas. It is already too late to gain an adequate idea of natural conditions in even recently settled portions of the globe. Wallace has dwelt upon the comparatively scanty and unimportant results to natural history of most of the great scientific voyages of the various civilized governments during the present century, from which it has resulted "that the productions of some of the most frequently visited and most interesting islands on the globe are still very imperfectly known, while their native plants and animals are being yearly exterminated. * * * Such are the Sandwich Islands, Tahiti, the Marquesas, the Phillippine Islands and a host of smaller ones; while Bourbon and Mauritius, St. Helena and several others have only been adequately explored after an important portion of their productions has been destroyed by cultivation or the reckless introduction of goats and pigs." ('Island Life,' p. 7.)

Elsewhere he shows that the introduction of goats into St. Helena utterly destroyed a whole flora of forest trees, and with them all the insects, mollusca, and perhaps birds dependent upon them. And further, that "cattle will, in many districts, wholly prevent the growth of trees; and with the trees the numerous insects dependent on those trees, and the birds which feed upon the insects, must disappear as well as the small mammalia which feed on the fruits, seeds, leaves or roots." Many local American instances have been brought together by Mr. F. M. Webster in an important paper entitled 'Biological effects of civilization on the insect fauna of Ohio,' which comes to me as I write these closing lines.

But the purpose of this address has been to dwell solely upon the question of the spread of species, and I must not touch upon other topics, however closely akin. It seems to me that the practical point to which we must come, after summarizing all that has been shown, is that since so many species have been imported by pure accident, and have succeeded perfectly in becoming acclimatized, may not much be accomplished by wisely planned and carefully guarded

introductions? The somewhat haphazard but none the less important and skillful work of Albert Koebele, first for the United States government, afterwards for the State of California, and now for the Hawaiian government, is certainly an indication, taken in connection with what we have shown, that thorough experimental work with predaceous and parasitic insects promises, in especial cases, results of possibly very great value.

We wish no more destructive birds like the English Sparrow; we have no desire to make an American resident of the Indian Mongoos, nor have we any desire to import the Australian flying fox as a pet. Neither do we desire to allow any more European plants to escape from cultivation and emulate the Russian Thistle. But there are many absolutely beneficial insects of Palearctic regions which might flourish amongst us, and whose intentional introduction could not be harmful from any point of view, while they might be of the greatest service.

L. O. HOWARD.

WASHINGTON, D. C.

---

*PHYLOGENY AND TAXONOMY OF THE ANGIOSPERMS.**

IT is unnecessary for me to state at the outset, what is evident to every botanist, that it is as yet impossible to present a complete phylogeny of the angiosperms. Phytopaleontology is too young a science, and the materials with which it deals are as yet far too scanty to have given us direct evidence as to the phylogeny of all families of plants. No one can trace with great certainty from the fossil remains of plants yet discovered the genealogy of any considerable portion of the vegetable kingdom. It will be many a year before the direct evidence we so much desire will leave no considerable gaps to be filled by skillful interpolation. However, after making all due allowance for the imperfection of the record, there are many facts as to past vegetation which are well established. Thus we know that the earliest plants were simple, homogeneous-celled, aquatic organisms. We know that ferns and gymnosperms preceded angiosperms. We know that the angiosperms which first appeared were of lower types, and that the highest types known to-day were wanting until very late in geological time.

It is true, moreover, that we are not confined to the direct evidence furnished by the paleontological record. In the individual development of every plant (its ontogenesis) there is a recapitulation of its ancestral development (phylogenesis). A critical study of the development of the individual must throw light upon the past history of the species. When we know every step in the formation of each plant we shall be able to trace the phylogeny of every species. Here, again, we have to face the fact that our knowledge is still quite fragmentary and that on this account the results are not as definite as we could wish, and yet, when we bring together what we know of the ontogeny of plants here and there in the higher groups, we are able to make out with much certainty not a little as to their phylogeny. To the details regarding these results I will advert somewhat later.

There is still another line of inquiry open to us, namely, the morphological, in which account is taken of the varying development of homologous tissues, members and organs. Rightly interpreted, the results of morphological studies are of very high importance in determining genetic relationships. When differences in homologous parts are regarded as but the expression of variation from a common form they beome indices of relationship, and when

*An abstract of the address of the retiring president, delivered before the Botanical Society of America, Toronto meeting, August 17, 1897.

these indices, obtained from all the tissues, members and organs of a group of plants, are judiciously considered they mark out lines of descent with great distinctness.

We have thus open to us three lines of investigation in the study of the phylogeny of plants, namely: (1) the historical, in which the materials are supplied by phyto-paleontology; (2) the ontogenetic, in which the development of the individual supplies us with the necessary data; and (3) the morphological, in which the different development of homologous parts is our index of relationship. In this paper I propose to bring these three lines of investigation to bear upon the problem of the phylogeny of the angiosperms. * * * *

From all the foregoing we may pretty safely proceed to construct the hypothetical phylogeny of the angiosperms, to serve as the basis of their taxonomy. And let it be fully understood that this is not presented as final, or as entirely satisfactory; it is merely a working hypothesis which claims no other merit than that of an attempt at conformity to the suggestions, sometimes faint, sometimes doubtful, from paleontology, from embryology (ontogeny) and from morphology. That some of these suggestions have been misinterpreted or that others have been overlooked is altogther likely, but in this I beg the indulgence of systematists, who may well realize the difficulties surrounding the problem here undertaken.

HYPOTHETICAL PHYLOGENY OF ANGIOSPERMS.

The angiospermous phylum parted very early into two sub-classes, the Monocotyledons and Dicotyledons. This separation took place while the flower strobilus was still apocarpous, and before any of the strobilar leaves had undergone much if any modification. At this stage the vegetative characters of the sporophyte were so well established that no profound modifications have been undergone since.

The modifications which gave us the main lines of monocotyledons were, first, the fusion of the carpels with one another and the production of a syncarpium, and second, the progressive fusion of the syncarpium with the other strobilar leaves. These resulted in the phylum which begins with Apocarpæ and passes to Coronarieæ, Epigynæ and Microspermæ. In some Apocarpæ and many plants of the type of the Coronarieæ the perianth has been more or less reduced (by aphanisis), in some cases amounting to complete suppression, as in palms, aroids, and sedges and grasses.

The primitive dicotyledons were apocarpous plants which soon developed along two diverging lines, characterized in the one case by the tendency of the leaves of the strobilus to fuse with each other in a transverse direction (transverse symphysis), while in the other the tendency was to a fusion of the leaves in two directions (transverse and longitudinal symphysis). The phylum resulting from the predominance of transverse symphysis began with the apocarpous Ranales, soon developing into the syncarpous Caryophyllales and Malvales. The type of the Caryophyllales became slightly modified in the Primulales by the transverse symphysis of the inner perianth-whorl, resulting in gamopetaly.

In the Polemoniales the type of the Primulales began to undergo modification by aphanisis, resulting in a reduction of the microsporophylls to five, and the carpels in the syncarpium to two or three. Increasing aphanisis produced the Personales and Lamiales with their four or two microsporophylls and irregular perianth, and in the latter group with each carpel restricted to the production of but one or two macrosporangia.

The phylum in which both transverse and longitudinal fusion are well marked proceeds from the apocarpous roseworts to the syncarpous saxifrages of the Rosales,

to the Celastrales in which epigyny is sometimes attained, thence to the Umbellales, where epigyny is constant, and to the Rubiales in which gamopetaly has become a fixed character, culminating in the group of the Asterales with its greatly reduced bicarpellary syncarpium.

Early predominance of aphanisis in some members of the Ranale phylum soon gave rise to the apetalous laurels and nutmegs from the buttercup type. A somewhat later appearance of aphanisis gave rise to the willows, amaranths and buckwheat from the pink type, and the spurgeworts and nettleworts from the mallow type. Similarly, early predominance of aphanisis in the Rosale phylum gave rise to the apetalous plane-trees from the rosewort type, while its later appearance gave rise to the proteads, daphnads, oleasters, sandalworts and loranths from the holly type, and the walnuts, oaks and galeworts from the horsechestnut type.

Early predominance of symphysis gave rise to the peculiar group of the myrtles from the rosewort type, in which by later aphanisis came the hippurids, birthworts and vine-rapes. The Parietales and Polygalales are later developments more or less parallel to the Caryophyllales, while the Geraniales and Guttiferales stand in a similar relation to the Malvales.

TAXONOMY OF ANGIOSPERMS.

As a result of the investigation of phylogeny along the lines of paleontology, embryology and morphology, the following suggestions as to the classification of angiosperms are made :

The angiosperms are separable into two diverging sub-classes, the monocotyledons (Monocotyledoneæ) and the dicotyledons (Dicotyledoneæ), the first ranking structurally lower than the second. The monocotyledons are well divided by Bentham and Hooker into seven series, and these we may accept unchanged with the single exception that the waterworts (Hydrocharitaceæ) should probably be removed from the Microspermæ, to constitute an additional coordinate group. These eight groups, which appear to be deserving of no more than ordinal rank, should then be re-arranged so as to have the following sequence, namely: Apocarpæ, Coronarieæ, Nudifloræ, Calycinæ, Glumaceæ, Hydrales, Epigynæ, Microspermæ. Here it must be understood that the Nudifloræ, Calycinæ and Glumaceæ are separate orders radiating from the present order Coronarieæ, and that the Hydrales constitute a diverging order from the base of the Epigynæ.

The choripetalous and gamopetalous dicotyledons are divided by Bentham and Hooker into six 'series,' one of which, the Discifloræ, should be broken up and its families distributed elsewhere. The remaining 'series,' which appear to have the rank of orders, form two somewhat diverging genetic lines or phyla, each beginning with apocarpous, hypogynous, choripetalous plants, and both attaining syncarpy and gamopetaly, one remaining hypogynous, the other becoming epigynous. An attempt has been made to distribute all the apetalous plants, these having been assigned places in the lower two orders. Since gamopetaly has evidently been attained at more than one point, it is no longer desirable to retain the Gamopetalæ as a distinct group. It must constantly be borne in mind that these orders and their sub-orders, as well as the families, are diversely related to one another, sometimes serially, but more commonly divergently, as the twigs of a tree are related, now by direct extension, and then by lateral branching.

Class ANGIOSPERMÆ.

Sub-class MONOCOTYLEDONEÆ.
 Order Apocarpæ (3 families).
 Order Coronarieæ (8 families).
 Order Nudifloræ (5 families).

Order Calycinæ (3 families).
Order Glumaceæ (5 families).
Order Hydrales (1 family).
Order Epigynæ (7 families).
Order Microspermæ (2 families).
Sub-class DICOTYLEDONEÆ.
Order Thalamifloræ.
Sub-order Ranales (12 families).
Sub-order Parietales (12 families).
Sub-order Polygalales (4 families).
Sub-order Caryophyllales (13 families).
Sub-order Geraniales (11 families).
Sub-order Guttiferales (6 families).
Sub-order Malvales (11 families).
Order Heteromeræ.
Sub-order Primulales (4 families).
Sub-order Ericales (7 families).
Sub-order Ebenales (4 families).
Order Bicarpellatæ.
Sub-order Polemoniales (5 families).
Sub-order Gentianales (6 families).
Sub-order Personales (8 families).
Sub-order Lamiales (4 families).
Order Calycifloræ.
Sub-order Rosales (12 families).
Sub-order Myrtales (9 families).
Sub-order Passiflorales (6 families).
Sub-order Celastrales (13 families).
Sub-order Sapindales (8 families).
Sub-order Umbellales (3 families).
Order Inferæ.
Sub-order Rubiales (2 families).
Sub-order Campanales (3 families).
Sub-order Asterales (4 families).

CHARLES E. BESSEY.
THE UNIVERSITY OF NEBRASKA.

BOTANICAL SOCIETY OF AMERICA.

THE most successful meeting which this young but flourishing society has yet held has just closed at Toronto. Although only three years old, both the attendance at the meeting and the great variety and strength of the papers read would be worthy of a much older organization. Every facility was afforded to the Society, through the courtesy of the Local Committee of Arrangements for the meeting of the British Association. The sessions, presided over by Dr. John M. Coulter, were held in the lecture hall of the handsome Biological Building in which this department of the University of Toronto is quartered. Besides the members, there were present a considerable number of British, Canadian and United States botanists. Foreign botanists had been invited by the Council to sit as associate members of the Society for this meeting. Among those present were Professor H. Marshall Ward, Professor F. O. Bower, Mr. Harold Wager, Mr. J. Bretland Farmer and Mr. J. Reynolds Green.

The officers of the Society are elected by ballots distributed by the Secretary by mail, and returned to him by the members. The Council canvassed the vote for officers and announced at the first meeting of the Society that the following had been elected for the year 1898: President, N. L. Britton, of New York; Vice-President, J. C. Arthur, of Lafayette, Ind.; Secretary, C. R. Barnes, of Madison, Wis.; Treasurer, Arthur Hollick, of New York; Councillors, B. L. Robinson, of Cambridge, Mass., and F. V. Coville, of Washington.

A very cordial invitation was sent by the Director and Trustees of the Missouri Botanical Garden urging the Society to hold a meeting in the spring of 1898 at the Garden, as their guests. The Society was obliged reluctantly to decline this invitation, inasmuch as it desires to cooperate with the A. A. A. S. at its semi-centennial next August in Boston, and it was not felt expedient to hold two meetings so close together.

The proposal to amend the constitution so as to reduce the dues met with no favor. It was unanimously laid upon the table, as was also the proposition to establish one or more medals to be awarded for valuable research. The discussion over the last proposition brought out the fact that the Society prefers to expend such funds as it receives for the promotion of research rather than for its reward.

Nine new members were elected. To

secure membership a candidate is first proposed by three members of the Society, who vouch for his eligibility under the constitution, which requires that he be actively engaged in research and the author of at least three contributions to knowledge in botanical lines. After notice of his candidacy has been sent to all members of the Society, written objections to him may be filed with the Secretary by any member. The Council then considers the candidates proposed and recommends such as it thinks proper. These names are then presented to the Society. One-fifth of the votes cast, if negative, will defeat any candidate.

The address of the retiring President, Dr. Charles E. Bessey, of the University of Nebraska, was delivered on Tuesday evening. A full abstract of the address is printed elsewhere in this number.

The following papers were read at the opening sessions on Wednesday:

B. L. ROBINSON: A case of ecblastesis and axial prolification in *Lipidium apetalum*.

J. C. ARTHUR: Movement of protoplasm in cœnocytic hyphæ.

JOHN M. COULTER: Pollen grains and antipodal cells.

FREDERIC E. CLEMENTS (presented by C. E. BESSEY): The transition region of the Caryophyllales.

D. P. PENHALLOW: A revision of the species *Picea* occurring in northeastern America.

EDWARD L. GREENE: Bibliographic Difficulties.

WILLIAM FAWCETT: The botanical gardens of Jamaica. Read by title.

Mr. Fawcett, finding himself unable to be present, sent his paper by post, but it unfortunately was not received in time to be presented. The Council had invited Drs. D. T. MacDougal and D. H. Campbell to present, in connection with this paper, their report upon the island of Jamaica as a site for the proposed tropical laboratory. It was intended that Dr. Fawcett's account of the botanic gardens should present, by means of lantern illustrations, an idea of the facilities already provided there. Although obliged to forego this, Dr. MacDougal spoke of the physical features and climate of the island, and Dr. Campbell discussed its botanical resources. The great interest with which the report was listened to indicates the desire which every botanist feels to have this proposed laboratory in early operation.

The Council also invited Mr. Herbert J. Webber to present before the Society an account of his remarkable discoveries in connection with the fertilization of Zamia. Mr. Webber spoke of the development of the pollen tube and of its spermatozoids and of the way in which they effect the fertilization of the egg. After the meeting Mr. Webber displayed the preparations in which he had made his discoveries. These were examined with the greatest interest.

It will be seen by an inspection of the foregoing list that the papers presented touched all of the great fields of botanical science, with the exception of phyto-geography. Sessions of two hours in the morning and three and a-half in the afternoon were barely sufficient for the completion of the program. At the next meeting, which is to be held in Boston in connection with that of the A. A. A. S., the reading of papers will probably have to be begun a day earlier.

C. R. BARNES,
Secretary.

THE INTERNATIONAL MATHEMATICAL CONGRESS.

THE meeting at Zurich, August 9th–11th, of the International Congress of Mathematicians was in every way a success. More than two hundred members took part. America sent seven representatives, including, however, three Cambridge graduates, now transplanted to Pennsylvania, Profes-

sors Harkness, Morley and Charlotte Scott. The greatest mathematician in the world, Sophus Lie, was not expected; and the greatest French mathematician, Poincaré, though down for a speech, did not come; but the actual program was particularly rich and interesting.

It is very noteworthy that the Congress was divided into five sections: (1) Arithmetic and Algebra; (2) Analysis, and Theory of Functions; (3) Geometry; (4) Mechanics and Mathematical Physics; (5) History and Bibliography.

The program of the first section contained the only title in English: 'On Pasigraphy, its present state and the pasigraphic movement in Italy,' by Ernst Schroeder, of Karlsruhe, author of 'Algebra der Logik.'

The second section contained a title from Z. de Galdeano, whose heroic efforts gave Spain a Journal of Mathematics, now unfortunately dead in the decadence of that beautiful, priest-ridden land.

The program of the third section, the only one consecrated wholly to a single title, Geometry, contained two titles on the non-Euclidean geometry.

Burali: Les postulats pour la geométrie d'Euclide et de Lobatschewsky.

Andrade: 'La statique non euclidienne et diverses formes mécaniques du postulatum d'Euclide.

In Section IV. Stodola treated an important subject, 'Die Beziehungen der Technik zur Mathematik.'

In the fifth section Eneström gave an important discussion of bibliography, a point where the Congress can and will render aid of fundamental importance.

In the first general assembly Rudio spoke on the aim and organization of international mathematical congresses.

It was determined that the next Congress should take place at Paris in 1900, under the auspices of the Société mathématique de France.

As aims were specified: (1) to promote personal relations between mathematicians of different lands; (2) to give, in reports or conferences, an aperçu of the actual state of the divers branches of mathematics, and to treat questions of recognized importance; (3) to deliberate on the problems and organization of future congresses; (4) to treat questions of bibliography, of terminology, etc., on subjects where an *entente international* appears necessary.

Rudio mentioned the yearly issue of an address-book of all mathematicians of the world with indication of their specialties; also of a biographic dictionary of living mathematicians with portraits; also of a literary journal for mathematics.

At the second general assembly Peano gave a conference: 'Logica matematica;' and Felix Klein a conference on teaching higher mathematics.

Three important resolutions were introduced by Vasiliev, of Kazan; Laisant, of Paris, and G. Cantor, of Halle, constituting: (1) a commission for preparation of general reports; (2) a standing bibliographic and terminology commission; (3) a commission to give the congress a permanent character by archives, libraries, stations for correspondence, editing or publishing noteworthy works, etc.

Surely this Congress has proven that it came only in the fullness of time, and that the world moves!

GEORGE BRUCE HALSTED.

AUSTIN, TEXAS.

CURRENT NOTES ON ANTHROPOLOGY.

NEW MUSEUM PUBLICATION.

IN May appeared 'Bulletin Number 1,' of the Free Museum of Science and Art, Philadelphia, a neat octavo of fifty pages, with illustrations. The announcement states that it will be published four times a year, at the subscription price of one dollar

a year. It will contain 'a résumé of the collections made by the Museum, notices of publications referring to museum work, and brief papers by the officers of the Museum.'

The present number contains two such papers, both by myself, one on 'The Pillars of Ben,' which are some curious monoliths in Chiapas, and the other on the Greek *Murmex* (referred to in SCIENCE, April 16, 1897). The notes on the accessions to the Museum are edited by Mr. Stewart Culin, the Director, and are arranged geographically. They present descriptions with cuts of a curious carved pebble from the Delaware valley, a horn arrow-straightener from the Pueblo Indians, name tablets from Corea, an inscribed stone from the thirteenth Egyptian dynasty described by the curator, Mrs. Sara Y. Stevenson, and a number of other interesting specimens.

Such a publication will be not only creditable to the Institution, but will prove a valuable reference work for students in archæology and ethnography.

BOTANY OF THE KLAMATHS.

A RECENT publication of the United States Department of Agriculture is a paper on the plants used by the Klamath Indians of Oregon, by Mr. Frederick V. Coville. It well illustrates how closely the aborigines studied their plant environment and drew their supplies from the vegetable world to the full extent that it was capable of furnishing. Mr. Coville gives the native names for more than a hundred species, all of which were utilized for food, clothing, dyeing, tool-making, 'medicine,' smoking, etc. He succeeded in identifying all the plants in use, and also obtained the native designations from educated Klamaths. He gives these with the diacritic marks used in the Century Dictionary; though it would have been better to have had recourse to the orthography adopted in the Klamath-English Dictionary, published by the United States Geographical Survey in 1890.

D. G. BRINTON.

UNIVERSITY OF PENNSYLVANIA.

NOTES ON INORGANIC CHEMISTRY.

THE *Revue Universelle des Mines* contains in the last number an article by Franz and Büttgenbach on the saline deposits of northern Germany in which a very full description is given of the Stassfurt salt beds. Twenty-five different mineral species are found in these deposits, of which the most important are the sylvine and kainite, so extensively used as fertilizers. The mean thickness of the potassium salt beds is at least twenty meters, and the quantity is estimated at ten billion tons. About three million tons are mined annually, so that at the present rate the supply would last thirty-three centuries.

THE British Home Office has issued an amendment to their order of February last, regarding the keeping of calcium carbid. The new order permits the keeping of quantities less than five pounds provided it is hermetically sealed in closed metal vessels containing not more than one pound each. Unless so kept no quantity whatever may be held without a license. Such restrictions, which are not peculiar to Great Britain, illustrate one method of powerful corporations to stifle competition. It appears that these orders result not so much from the intrinsic danger in calcium carbid as from a fear, on the part of those interested in gas, oil and electric lighting, of rivalry in the use of acetylene.

G. P. DROSSBACH discusses in the *Journal für Gasbeleuchtung* the fact that, while pure thorium oxid has a feeble glow in the Bunsen flame, when a per cent. or less of cerium oxid is present the light is increased ten or twelve fold. He attributes the ac-

tion of the cerium oxid to 'resonance;' the vibrations of the thoria molecules are not synchronous with those of the Bunsen flame, but the presence of a small amount of ceria brings them in accord, as a bit of wax will bring into accord two tuning forks of slightly different pitch. This, Drossbach thinks, is the reason that the mantles for the Welsbach burner must contain ceria as well as thoria.

In the *Ztsch. angewante Chemie*, Lunge and Millberg add a fresh chapter to the controversy regarding the solubility of quartz powder in alkalies. They find that the solubility depends very largely on the fineness of the powder; if fine enough the quartz dissolves completely in both caustic soda and caustic potash on boiling, and the carbonates exercise a decided solvent action. Since clays and similar derived material contain crystallized silica in a state of extremely minute subdivision, there is hence no method now known of accurately determining the proportions of crystallized and amorphous silica present.

In January last at Hannover, after a period of cold weather, there fell on the rising temperature a snow in the form of compact balls. Many of these balls were simple and completely transparent, and consisted of single, simple, spherical crystals. These are described by F. Rinne in the *Jahrbuch für Mineralogie*. Apparently they were crystallized rain drops, but all efforts to make them artificially were without result. They resembled the chondrites of many meteorites, and these also Dr. Rinne finds it impossible to form artificially.

W. Stelzer in the *Pharm. Centr.-Halle* records the examination of several solvents for ozone. Olive oil dissolves 100 volume per cent. of ozone, and this preparation is manufactured by Spranger, of Berlin, under the trade name of 'electron.' Codliver oil takes up 200 volume per cent. ozone, and loses thereby its disagreeable taste and odor. Spranger's 'tincture of ozone' is a solution of ozone in terpene and is probably a chemical compound. One sample examined had lost little of its ozone in fifteen months. Fats and oils which contain no oleic acid and which do not absorb iodin, such as vaseline and other petroleum oils, do not dissolve ozone.

J. L. H.

SCIENTIFIC NOTES AND NEWS.

The prize established by the city of Moscow to be awarded at each International Medical Congress for the medical work of greatest benefit to mankind has been bestowed by the present Congress on M. Henri Dunant, the founder of the Red Cross Society.

Professor von Kölliker, of Würzburg, who recently celebrated his eightieth birthday and the fiftieth anniversary of his appointment as professor, has been awarded the gold Comenius medal of the Imperial Leopold-Carolina Academy of Halle.

It is proposed to erect a tablet in honor of Professor Giuseppi Sanarelli, the discoverer of the microbe of yellow fever, at the University of Sienna, of which he is an alumnus.

The death is announced, at the age of sixty-nine years, of Dr. Jules Bernard Luys, known for his researches on the brain and nervous system, and less favorably for his publications on hypnotism and telepathy.

We regret also to record the death of Mr. Isaac N. Travis, taxidermist and naturalist in the American Museum of Natural History, New York.

Mr. W. W. Woolen proposes to present to the city of Indianapolis fifty-six acres of land for a botanical garden and an ornithological preserve.

The late Marshall Harris bequeathed $60,000 for a public library in Oshkosh, Wis., on condition that an equal amount be collected, and ex-Senator Sawyer, of Wisconsin, has subscribed $25,000 towards the amount.

Emperor Francis Joseph, of Austria, has given his consent to the union of the two great

imperial libraries at Vienna, the Hofbibliothek and the Private Imperial Library. The latter has not hitherto been opened to the public. It possesses a famous collection of portraits, said to exceed 200,000 in number.

As many of the fish brought to the New York Aquarium have died from the effects of injuries received in transit, it has been decided to establish a fish hatchery as one of the departments of the aquarium.

MR. JAMES PERRY has brought suit against the American Museum of Natural History to recover a balance of $400,612.75 with interest, which he alleges to be due him for an archæological and ethnological collection purchased by the Museum.

DR. CHARRIN has been appointed director of a laboratory of experimental medicine which has just been established in the Collège de France.

A BACTERIOLOGICAL Institute has been established at Mons, Belgium, by the Provincial Council, which gives it a subsidy of 6,500 fr. 10,000 fr. have been given to the Institute by an anonymous donor.

THE ninth International Congress of Hygiene and Demography will be held at Madrid from the 10th to the 17th of April of next year.

THE Australasian Chamber of Mines in London are making arrangements for an International Mining Machinery and Metallurgical Exhibition to be held in London in 1899, in time for the exhibits to be forwarded to the Paris Exposition in 1900.

THE partial cessation of the plague at Bombay has been followed by an epidemic of cholera, which seems not to have attracted much attention. During the last week for which advices have been received there were 220 deaths from cholera. There were still during that week 18 deaths from the plague.

THE British Medical Association held its sixty-fifth annual meeting at Montreal last week, following the program which has been already published in this JOURNAL. At the first session, on the afternoon of Tuesday, August 31st, addresses of welcome were made by Mr. Wilson Smith, mayor of the city; by Mr. Adolphus Chapleau, Lieutenant-General of the Province of Quebec, and by the Earl of Aberdeen, Governor-General of Canada, and Dr. T. G. Roddick delivered the President's address. Dr. Roddick, after welcoming the members and guests, referred to the history of the Association from its foundation at the initiative of Sir Charles Hastings in 1832, and then considered especially the Canadian climatic conditions and health resorts, and concluded with a review of medical education and medical legislation in Canada. On the following afternoons, Wednesday, Thursday and Friday, the general addresses were given. The address in medicine was given by Professor William Osler, of Johns Hopkins University, who, it appears, is still a Canadian citizen. His address was entitled 'British Medicine in Greater Britain,' and took a wide survey, including a comparison of the Greek and British races and the influence of the former on the latter. The address in surgery was by Dr. W. Mitchell Banks, Liverpool, who confined his address to the work accomplished by military surgeons. The address on public medicine, given on Friday afternoon, was by Dr. H. M. Biggs. A general address was given by Professor Charles Richet, who chose as his subject 'The work of Pasteur and the Modern Conception of Medicine.' During the mornings sessions of the Sections were held. The Proceedings, to be published in the *British Medical Journal*, will bear witness to many important addresses, papers and discussions. At a special session of convocation McGill University conferred the honorary degree of LL.D. on Lord Lister, Sir W. Turner and Drs. Broadbent, Gaskill, McAllister, Watson Cheyne, Henry Barnes and A. G. Wheelhouse.

THE continuity of national associations for the advancement of science is exemplified by the fact that the German Association, which meets in Brunswick in September, has been invited to make an excursion to Pyrmont, where its seventeenth meeting was held in 1839.

EIGHT hundred geologists were in attendance at the recent International Geological Congress, of whom about two hundred and fifty were Russians. No reports of the meetings have been cabled to the daily papers, but we hope to pub-

lish shortly an article on the work of the Congress.

THE American Social Science Association held its general meeting in Saratoga last week. Mr. Frank B. Sanborn, who for more than twenty years has been Secretary of the Association, on resigning, presented a report tracing the history of the Association, which he thought was not accomplishing as much as it should. A number of interesting papers were, however, presented at the Saratoga meeting. Judge Simeon E. Baldwin, New Haven, was elected President and Mr. F. Stanley Root, New Haven, Secretary.

THE French government proposes to send an official expedition to Egypt, starting from Marseilles on October 28, 1897, and returning in the month of December. The expedition will be under the direction of Professor Révillont. Volunteers willing to pay their own expenses will be allowed to join. The arrangements are in the charge of M. Maurice Junot, of Rue de Rome, Paris.

WE learn from *Natural Science* that Mr. George Murray and Mr. V. H. Blackman have returned from their trip to Panama, after a successful and profitable voyage. They have obtained a large quantity of plankton containing many new specimens, which will shortly be worked out, and have made numerous interesting observations on living forms. They spent two or three days in Jamaica on the way.

PROFESSOR KOCH, so it is reported, is about to return to South Africa to carry out further experiments in relation to rinderpest.

PROFESSOR CHARLES S. PROSSER, of Union College, has been engaged during the past summer in mapping and describing the Upper Devonian formations of southeastern New York for the New York Geological Survey.

THE *Botanical Gazette* states that Drs. Farlow and Coulter will make, during the winter, a further examination in the West Indies with a view to finding a suitable site for a botanical tropical laboratory.

AN illustrated monthly of popular botany, *The Plant World*, will be published by Willard N. Clute & Co., Binghamton, N. Y., beginning October 1st. The editor is Dr. F. H. Knowlton, United States National Museum.

ON September 3rd Professor Nef gave a public address at the University of Chicago on 'The Problems of Organic Chemistry,' and on September 7th and 8th Professor Lester F. Ward was announced to give two lectures, one on 'The Founder of Sociology, Auguste Comte,' the other on 'Nature and Nurture.'

PROFESSOR SKLAREK, Halle, calls our attention to the fact that among the publications of the late W. Preyer, given on page 252 above, 'The Five Senses of Man' was included. The book is by Professor J. Bernstein, of Halle.

WE are glad to receive the information that 'The Louisiana Society of Naturalists' was organized on July 22d. The Society will not only undertake to encourage and advance the study of natural science, but will also establish a library and a museum, and will publish its proceedings. The Society is to be incorporated and starts with about 45 members, nearly all of whom are workers in some branch of natural science. The first officers are:

President, Professor J. H. Dillard, Tulane University; *Vice-Presidents*, Mr. G. R. Westfeldt, Professor H. A. Morgan, Louisiana State University, Rev. A. B. Langlois; *Secretary-Treasurer*, Mr. E. Foster; *Executive Committee*, Professor J. H. Dillard, Professor G. E. Beyer, Mr. G. R. Westfeld, Dr. O. Joachim, Professor H. A. Morgan, Mr. J. C. Smith, Rev. A. B. Langlois, Mr. E. Foster.

MR. H. C. FAIRBANKS, of Sibley College, while reconstructing a gas-engine, observed a singular though probably not exceptional phenomenon which, so far as known, has not been previously described. The machine exhibited a great loss of heater-efficiency, which was unaccounted for and was not affected by any changes made in the process of general repair. Finally it was suspected that the conductivity of the metal of the cast iron 'fire-pot' had been impaired by oxidation or otherwise, and it was replaced by a new one. The engine at once started off at full power and regained its original efficiency.

At the request of the daughters of George Bond, Professor Holden, Director of the Lick Observatory, has undertaken to arrange the manuscript material in their hands in an orderly form. The work will be entitled 'Memorials of William Cranch Bond, Director of the Harvard College Observatory, 1840–59, and of his Son, George Phillips Bond, Director of the Harvard College Observatory, 1859–65,' and will be sold for two dollars by C. A. Murdock &. Co., 532 Clay Street, San Francisco, and by Lemcke & Büchner, 812 Broadway, New York City. The contents are: Chapter I., Life of W. C. Bond, 1789–1859; II., Life of G. P. Bond, 1824–1865; III., Selections from the Diaries of George Bond; IV., Selections from the Correspondence of George Bond; V., Account of the Scientific Work of the Bonds; Appendices, giving a complete list of their published writings; and Index of Proper Names. The book will be well illustrated. It is hoped by the kindness of Professor E. C. Pickering, Director of the Harvard College Observatory, to reproduce two fine steel engravings of the Great Comet of 1858 and of the nebula of *Orion*, from the plates of the *Annals* H. C. O.

The British Museum (Natural History) has acquired, says *Natural Science*, the Savin collection of vertebrate remains from the Norfolk forest-bed and other deposits of that coast. A collection of gault fossils from the 300-feet level of the shaft of the Dover coal-fields has also been received, and it is understood that the whole of the remains from this very interesting and important shaft will be preserved for the national collections, as a typical reference series for the underground geology of the southeast of England.

UNIVERSITY AND EDUCATIONAL NEWS.

At the meeting of the corporation of Brown University on September 1st statements were presented by the Conference Committee and by President Andrews. He states that he has been reticent and careful in expressing views on the free coinage of silver by the United States; that he would discountenance any proposal which, in his judgment, bids fair to place the country's finances on a monetary basis of silver alone; that he has always insisted that the principal and interest of our public debt should be paid in gold, and that he had only publicly advocated that form of bimetallism which was a part of the Republican platform in the last election. He states further that his resignation was made on account of his desire to regard the University's interests and that the publication of the Committee's minutes did not proceed from his motion. As President Andrews simply cleared himself from the charges made by the Conference Committee and did not attempt to defend reasonable freedom of speech, we are especially glad that the corporation, in asking him to withdraw his resignation, stated that they did this "especially desiring to avoid, in the conduct of the University, the imputation even of the consideration of party questions, or of the dominance of any class, but that in the language of its charter, 'In this liberal and catholic institution all members whereof shall enjoy full, free, absolute and uninterrupted liberty of conscience,' which includes freedom of thought and expression, it cannot feel that the divergence of views upon the 'silver question' and of its effects upon the University between you and the members of the corporation is an adequate cause of separation between us." President Andrews has not yet made a reply to the letter from the corporation, but it is understood that he will not withdraw his resignation.

The executor of the will of the late Mrs. Lucy Fayerweather has brought suit in the United States Courts with a view to setting aside the decision of the State Courts awarding the estate of the late Daniel B. Fayerweather to the colleges to which it was bequeathed. The heirs-at-law are also contesting the will of the late William Lampson, who left most of his estate to Yale University, alleging that he was of unsound mind. We wish that the moral insanity which leads people to make these contests disqualified them at law from inheriting any money.

Dr. D. K. Pearson has presented Beloit college with a dormitory costing $30,000.

Yale University receives $5,000 by the will

of the late Miss Julia Lockwood for the foundation of a scholarship.

FUNDS given by friends of Smith College for a new dormitory will, it is said, be used for a chemical laboratory. It is hoped to secure some $30,000 for the building.

WE regret that the announcement made to the effect that Mr. S. B. Brownell had presented Barnard College with a building for a dormitory is incorrect. It had its origin probably in the fact that plans have been filed for the west wing of the new buildings of Barnard College, given by Mrs. Fiske, which will be temporarily used as a dormitory.

THE sixth annual summer school held at the University of Minnesota, Minneapolis, has just closed one of the most successful sessions of its history. The school is organized in two sections, an elementary section and a university section. The enrollment of the university section in the several scientific subjects was as follows:

General Chemistry; Professor Frankforter.......	40
Entomology; Mr. Oestlund	14
General Geology; Professor Hall................	38
Physiology; Professor Nachtrieb................	18
Plant Physiology; Mr. Ramaley................	12
Physics; Professor Jones.......................	30

AT the recent Zionist conference for the colonization of Palestine by the Jews at Bâle, a commission was appointed to report upon the establishment of a university at Jerusalem.

A SPECIAL commission will meet shortly at St. Petersburg to discuss the introduction of universal and compulsory education in Russia.

DISCUSSION AND CORRESPONDENCE.

OBSERVATIONS OF THE PASSAGE OF MIGRATING BIRDS ACROSS THE LUNAR DISK ON THE NIGHTS OF SEPTEMBER 23 AND 24, 1896.

THE time is at hand when records of the transit of migrating birds across the moon's face may be secured, and I desire to put on record the following measurements, made last year, which may be of assistance to observers. All records show that the migration takes place at night, at least in the case of the smaller birds, and the dates immediately preceding and following the full of the Moon, with probably a certain amount of latitude for weather and temperature, are the ones chosen.

The instrument used in these observations was the finder of the equatorial of the Ladd Observatory. Its aperture is 4 inches, and the magnifying power was 40 diameters. When focussed on the Moon, the eye-piece had to be pulled out 1.74 inches, and the principal focal length was 4 ft. 9.59 ins.

The observations may be divided into three groups:

a. 7:45 to 8:15 Eastern M. T., Sept. 23d.
b. 8:15 to 9:15 " " " "
c. 7:45 to 8:15 " " " 24th.

The apparent altitudes and azimuths of the Moon were:

Sept. 23, 7:45,	altitude =	19°.0,	azimuth	N. 88°.0 E.
" " 8:15,	"	24°.6,	"	S. 87°.1 E.
" " 9:15,	"	35°.4,	"	S. 76°.8 E.
Sept. 24, 7:45,	"	14°.6,	"	N. 79°.9 E.
" " 8:15,	"	19°.8,	"	N. 82°.3 E.

The mean altitudes were:

Period *a* (½ hour) 21°.8 above the true horizon.
b (1 hour) 30°.0 " " " "
c (½ hour) 17°.2 " " " "

Journal of Observations.

The flights were so rapid that it was thought best to attempt nothing more than hasty comparisons with prominent lunar features in order to get estimates of the apparent size of the birds. Three points were selected for this purpose:

Aristarchus	(longer inside diam.) approximately	0′.3
Copernicus	" " " "	0′.6
Mare Crisium	" " " "	3′.0

Times were estimated by a chronometer audibly beating half seconds.

First night, September 23d. From 7:45 to 8:15 scarcely a minute passed without the passage of several birds, in groups numbering from one to five or six in immediate succession. It was obvious that the birds traveled in little companies. After perhaps a minute without any, one would appear, followed by four or five more in the next ten seconds—perhaps members of one family keeping near each other to relieve the loneliness of the long journey. The great majority traveled from north to south. Few deviated more than 20° or 30° from this

direction, and none were seen to move in the opposite direction. The majority were less than one-half second in crossing the Moon's disk (diameter $= 29'.5$). Quite a considerable number traversed the disk in 0.1 or 0.2 second. Few were as slow as 1 second and only one required 2 to 3 seconds. In this case the trajectory may have approached the line of sight. A majority appeared very small, not larger than Aristarchus (or $0'.3$); few equaled Copernicus (or $0'.6$); one only had a spread of wings equal to the longer diameter of the Mare Crisium (or $3'.0$). In this case the wings were sharply seen when the focus was $0'.21$ longer than the principal focal length. For most of the birds the focus scarcely required changing from that for the Moon's surface. Some of the swiftest flights were made by birds of the smallest apparent size.

After 8:15, as the moon rose higher (altitude 25° to 35°), the number of birds diminished; and at 9:15 intervals of 2 to 5 minutes elapsed between successive birds. The travelers no longer came in groups. Evidently the angular area of the Moon no longer filled the distance between the mean trajectories of the members of a group. The average size was larger, more nearly that of Copernicus; one bird, badly out of focus, equaled the Mare Crisium in size.

At 9:15 the observations were discontinued, as the intervals were continually getting longer.

Second night, September 24th. The watch was commenced at 7:45 with the Moon at a lower altitude than on the previous evening. The birds were less numerous, and after a half hour at 8:15, clouds began to gather, which soon completely covered the sky. In this half hour not over a dozen birds were seen. Two of these moved from south to north, traversing the diameter of the lunar disk in about 3 seconds. These were the only birds seen flying north on either evening, and the slowness of their speed indicates that they were probably moving more nearly in the line of sight (or east and west). Every flutter of the wings was plainly visible with the telescope at its lunar focus. One bird, of an expanse equal to that of the Mare Serenitatis, was blurred beyond recognition, and was evidently close at hand. One had the wavering flight of the goldfinch, and a diameter equaling that of Aristarchus (or $0.'3$).

It seems possible that the prospect of cloudy weather may have deterred the migrating birds from starting on this evening. The interval from sunset to moonrise was also longer (48 minutes as against 24 minutes on the previous evening).

I now proceed to the reduction of these estimates, taking first the case of the single bird whose motion was slow enough to permit an exact adjustment of the focus, the focal length having to be increased for the bird from 57.59 inches to 57.80 inches. The bird was nearly end on. Assuming its real spread to have been 12 inches, and comparing its estimated angular diameter with the radius of a circle we have its

$$\text{distance} = \frac{3437.7}{3.0} = 1146 \text{ feet.}$$

Reversing the process, we have from the law of lenses,

$$\text{Conjugate focal length} = 1321 \text{ feet,}$$

which would make the spread

$$\frac{1321}{1146} + 12 = 13.8 \text{ inches.}$$

The spread of a robin is 16 inches, and the bird may have been of the size of a thrush.

The majority of the flights were at right angles to the line of sight, and the lengths of our smaller birds (warblers, flycatchers, etc.) being from 5 to 7 inches, I shall assume an average true size of 6 inches, and an apparent (angular) dimension of $0'.3$ in periods a and c, with a mean altitude of 20°; while towards the close of period b, the altitude had increased to 35°, and the mean apparent angular diameter began to approach $0'.6$. This gives for distances

$$\text{(a) and (c)} \quad \frac{3437.7}{0.3} \times \tfrac{1}{2} = 5729.5 \text{ feet,}$$

$$\text{(b)} \quad \frac{3437.7}{0.6} \times \tfrac{1}{2} = 2864.8 \text{ feet,}$$

and for the heights of the birds above the observer's level (235 feet above sea-level,

$$\text{(a) and (c)} \quad 5729.5 \times \sin 20° = 1959.6 \text{ feet,}$$

$$\text{(b)} \quad 2864.8 \times \sin 35° = 1643.2 \text{ feet.}$$

These measurements indicate an altitude of about 200 feet above sea-level as the average

height of the migratory flight of the smaller birds. Of course, if the dimensions were greater than those assumed, the altitudes must be correspondingly increased, but the largest bird, whose distance was determined by the focal adjustment already described, had an altitude above sea-level of

$$(1321 \times \sin 20^\circ) + 235 = 687 \text{ feet},$$

and was certainly much lower than the smaller birds.

The speeds can be roughly estimated from the times of transversing the lunar diameter (29′.5). This time was on the average about one-half second, giving

$$\begin{aligned} \text{velocity} &= \frac{29.5}{0.3} \times \tfrac{1}{2} \text{ ft. per } \tfrac{1}{2} \text{ sec.} \\ &= 98.4 \text{ feet per second,} \\ &= 67 \text{ miles per hour.} \end{aligned}$$

But the swiftest flights, with every allowance for the difficulty of their estimation, were at least twice as rapid, which, if the distance were the same, would imply a velocity of at least 134 miles per hour. Some of the swifter trajectories may have belonged to very small birds at lower altitudes and smaller distances, but I have already assumed a size which is nearly that of our smallest birds. Any increase in the estimate of size enlarges that of distance and velocity. I am not ready to admit the probability of an error of judgment in the estimation of apparent sizes of as much as 100 per cent, and I have already increased the more vulnerable time-estimate for the swiftest flight from 0.15 to 0.25 seconds. Judging from the appearance of many of these darting specks, and with every allowance for errors of estimation, I am of the opinion that some of these apparent velocities are real, and that certain small birds (not the swifter swallows, humming birds and swifts, for these have all gone a month before the dates in question) can maintain a flight of 100 miles per hour without being stripped of their feathers.

In SCIENCE for January 1, 1897 (Vol. 5 N. S., p. 26), Mr. H. H. Clayton gives the height of a flock of ducks, flying southwest in December, as 958 feet above the Neponset valley, and the velocity as 47.8 miles per hour; and in SCIENCE for April 9, 1897 (Vol. 5 N. S., p. 585), the same observer gives the height for a flock of geese, migrating northeastward in March, as 905 feet above the Neponset valley, or 960 feet above sea-level, and the velocity of flight as 44.3 miles per hour. It thus appears probable that the larger birds migrate at a lower altitude than the smaller ones, and at not over half the speed of the swiftest flights.

Even more remarkable than the speed of migration are the psychological problems involved in these semi-annual movements of enormous multitudes of creatures. There was, to me, something awe-inspiring in this spectacle of a throng of tiny beings launching out into the unknown deep, in pale moonlight and through the hours commonly given to sleep, flitting swiftly and unerringly to a far-off goal, while beneath, and heeding them not, slumbered a dreaming world. What mighty impulse of daring is this which can transform a timorous sparrow, content all day to hop from bough to bough near to its nest and mate, into a bold adventurer, starting out, Columbus-like, on a voyage of discovery? If it were a matter of individual courage and wisdom, we men might shrink from the comparison—the ardor, the inerrancy, are so superhuman. Rather must we liken the migratory impulse to an irresistible force, drawing the winged wayfarers into its current, and bearing them they know not whither. It must not be forgotten that for the young birds, constituting no small number of the host, this journey is absolutely new, and not the result of experience. If the movement were the result of knowledge and trust, we might well exclaim: Oh to be as confident of eternal beneficence, and as full of foresight as are these little wanderers!

PROVIDENCE, R. I., September 3, 1897.

SCIENTIFIC LITERATURE.

Year-book of the United States Department of Agriculture, 1896. [1897.]

In the preface to this volume, Mr. Charles W. Dabney, Jr., remarks that it falls far short of the ideal set for it, and regrets that it was not possible to give it more 'editorial revision' than it has received. We may all hope with

Mr. Dabney that each year-book will be better than its predecessors; but it seems to us that there is nothing to apologize for in the present work; and as for 'editorial revision,' we believe the mostly eminent writers of the articles it contains know perfectly well what they are about, and that revision of any sort would be an injury to them and a detriment to the volume. It is the proper work of the editor to obtain, select and arrange suitable articles for the volume, and this Mr. Dabney has done in a most admirable manner; but the time has come for scientific workers to insist on having their manuscripts printed as written, instead of being changed and even interlarded with gross errors, as is sometimes the case.*

The frontispiece of the year-book appropriately consists of the portraits of Senator Morrill and Hon. Wm. H. Hatch; the fine face of Senator Morrill is especially welcome, and will not easily be forgotten, even by those who have only seen the picture. The first part of the book, the report of Secretary Morton, has long been before the public, and need not be specially discussed now. It is, however, a document that should be read by all who take any interest in agriculture or agricultural science. The observations on the free distribution of seeds, and on the affairs of the experiment stations, will be endorsed by nearly all those who are not connected with the 'political machine.' Whatever opinion one may hold as to the propriety of the free distribution of seeds by the government, the present system must be condemned as wasteful and unjust. Whatever views one may have as to the desirability of local control, it cannot be permitted for experiment station authorities to break the letter or the spirit of the law, or waste the funds entrusted to them. The people of the United States, after all, are partners in business, and cannot wholly escape responsibility for one another's actions. It is, besides, a serious injury to the majority of stations, which are admirably applying their funds, that the minority should be able to drag the name of the experiment stations in the mud.

* Some readers will think this too strong a statement, but we could readily give the facts of the cases we have in mind. It may be added that those responsible for the errors were scientific experts of excellent standing, as learned as any that could be obtained, but they did not happen to know everything. The publications were not those of the Department of Agriculture.

The body of the book consists of thirty articles bearing on as many problems of agriculture and kindred arts, and while probably no living person is competent to sit in critical judgment on such a varied assortment, it will not be questioned that each essay is of great value. We think that any educated citizen of this country, turning over the pages, cannot fail to feel very proud of the volume, as affording evidence of the highly satisfactory condition of at least one of the great departments of the government. If he is acquainted with the official agricultural publications of other countries he will have the further satisfaction of knowing that the United States is leading, not following, in the matter of educating the agricultural population, for the year-book is as truly an instrument of education as any college or university.

Mr. H. J. Webber's article on the 'Influence of Environment in the Origination of Plant Varieties' is very interesting, though he does not directly meet the question whether acquired characters are transmissible, while apparently being of that opinion. Dr. C. W. Stiles' essay on 'The Country Slaughterhouse as a Factor in the Spread of Disease' is very opportune. Mr. Marlatt's 'Insect Control in California' is an extremely valuable article and will help to settle some hot disputes between entomologists and horticulturists. 'The Superior Value of Larger Heavy seed,' by Messrs. G. H. Hicks and J.C. Dabney, is not only of much practical value, but of considerable theoretical interest. It is impossible now to discuss the remaining articles, but special attention must be called to 'An Ideal Department of Agriculture and Industries,' by M. E. Tisserand, Councillor of State and Director of Agriculture in France. This is a most suggestive and interesting article, and we should express our thanks to Mr. Dabney for arranging for its publication in the year-book.

*THE SCIENCE OF HUMANITY.**

I.

HUMANITY is a favorite theme of poet and philosopher, novelist and historian, dramatist and moralist. The changes rung on the theme run the entire gamut of human feeling and thinking; its burden is caught in song and story and crystallized in books, and no sweeter strains have ever been sung, no grander scenes enacted, no nobler lines penned, than those fertilized by the touch of human (and solely human) nature that makes the whole world kin..

The chief subject of thought among all races is humanity in some of its numberless aspects; the chief part of the literature of civilized nations relates to humanity; the chief activities of all men are inspired by humanity. Yet—and this is a modern marvel—for the greater part the thought is vague, the literature random, the activity unorganized; *i. e*, this most important of all subjects-matter and objects-matter in human ken has hardly been brought into the domain of that definite knowledge called science. It is meet to inquire why this is so; and, to the end that the inquiry may be answered clearly, it is needful first to define humanity and then to consider what knowledge is and the way in which science has come to be; later the half-formed science

*Vice-Presidential address before Section H of the American Association for the Advancement of Science, delivered at Detroit, August 9, 1897.

of that which is proper to intellectual man and most important to his kind may be outlined.

II.

According to the lexicographer, humanity denotes: (1) the condition or quality of being human; (2) the character of being humane; (3) the character of being well bred; (4) mankind collectively, and (5) secular learning or literature.* The fourth of these definitions connotes Man—the genus Homo, object-matter of the broad science of anthropology—viewed in a distinct way, *i. e.*, as a mass or composite body rather than discrete individuals. The fifth definition connotes but a limited field in a vast domain, and is scholastic, if not archaic; with this sense the term is chiefly used in opposition to divinity, often in the plural form (though there is good precedent for the use of this plural form in a more general and at the same time a more definite sense).† The first three definitions connote a wide range of attributes of Man which, albeit well recognized by all intelligent people, are rarely reckoned among the objects-matter of anthropology, seldom included within the pale of science; yet it is these attributes that especially distinguish Man and set him apart from the mineral, vegetal and animal worlds, and exalt him above the rocks and plants and beasts of simple nature.

Although commonplace, these definitions are worthy of careful consideration in that they summarize the substance of intelligent thought since the beginning of writing—indeed, since its own beginning in the remote unwritten past—and particularly during the era of unprecedented intellectual activity and scientific progress dating from the issue of Bacon's *Novum Organum;* they carry the wisdom of the ages, and especially of these later days during which wisdom prevails as never before. Viewed separately or in connection with contemporary definitions relating to mankind, they indicate general (although vague) recognition of certain specific attributes of Man, not as an animal, but as an ill-defined something known as a human being. When the history of thought condensed into the set phrases of the lexicographer is scanned, it is found that bitter controversy has been engendered by the diverse aspects of Man as seen from opposite sides; the disputants, like the storied knights of old, have admired the object, one as silver and the other as gold, and have done doughty battle in defense of their one-sided vision; the biologist, with eyes trained by observation and reason sharpened by long study of living things, sees the silvern side and sounds trumpet for man as an animal, while the litterateur and statesman and philanthropist are half-dazzled by the golden glory of Man as a thing supernal. The fair conclusion is that both are right as to what they see and both wrong as to what they fail to see; and in the light of this conclusion it is clear—if the general judgment of the body of thinkers is worth anything—that man has an animal basis on which a noble superstructure is borne. The definitions of the lexicographer, who voices the thought of the world, show that among general thinkers the idea of humanity prevails over the idea of animality, while the current literature of science indicates that the idea of animality is dominant in scientific circles; indeed, some writers on anthropology, the Science of Man, restrict the term to knowledge of the mammalian order Bimana, a limitation excluding the essential characteristics of Man as a thoughtful and emotional being and as an integral part of a collective and interdependent assemblage. Any attempt to harmonize these opposing ideas must begin with definite

* Condensed and rearranged from the 'Standard' and 'Century' Dictionaries.

† *E. g.*, in 'The Humanities,' by J. W. Powell; SCIENCE, New Series, Vol. I., 1895, pp. 15–18.

statements of the meaning attached to the essential term by more catholic anthropologists. So Humanity may be defined, by exclusion, as the condition or quality or character of possessing attributes distinct from those of animals, vegetals and minerals; or, by inclusion, as (1) attributes or characteristics confined to human beings, comprising (*a*) the condition or quality of being human, *i. e.*, of acting, feeling and thinking after the manner of human beings, (*b*) the character of being humane, and (*c*) the character of being well bred; (2) mankind collectively; (3) secular learning and literature.

The supreme importance of humanity as thus defined is indicated by the fact that it is the foremost subject-matter of thought and speech and literature among all peoples, its prominence increasing from savagery through barbarism and civilization and culminating in enlightenment. The essential distinctness of humanity as thus defined appears when its serial relations to the other primary objects-matter of knowledge are considered. Just as living things rise above the mineral world by the possession of vitality, and just as animals rise above plants by the possession of motility, so do human beings rise above all other things by the possession of specific attributes rooting in mentality and maturing in the complex activities of collective life; or just as inorganic matter is the basis for the essentially distinct organic existence, so organic matter and processes form the basis for the essentially distinct superorganic activities of human existence. The importance and distinctness of humanity are, indeed, such that it behooves naturalists to recognize a fourth realm or world—to extend science from the great realms of the mineral, the vegetal and the animal into the incomparably broader and richer realm of the purely human; and this extension is the chief end of modern anthropology.

III.

Human knowledge is constantly increasing. The body or aggregate of knowledge is imponderable, and may not be counted or measured or weighed; yet it is an entity of prime importance and of universal recognition. Itself indefinite and varying from mind to mind, the sum of knowledge may be divided, albeit roughly, and analyzed, albeit crudely, and the days and years and centuries of its progress among men and peoples may be so studied that its tendencies, and perhaps even the laws of its growth, may be followed, albeit slowly and uncertainly. Although so indefinite, it is well worth while to try, and try again and still again, to analyze knowledge and trace its progress; for knowledge is the end and aim of intelligence, and human progress is measured not more by increase in knowledge of things than by increase in knowledge of knowledge.

Many students have found it convenient to divide or classify knowledge as individual and common, general and special, empiric and scientific, deductive and inductive, etc., according to the point of view; and these divisions are of use in that they represent first steps in analysis, though it is to be remembered that they are more or less vague or arbitrary, one or both. It may not be bootless slightly to extend this provisional analysis in order to trace more clearly the lines and stages in the growth of intellectual product.

For the sake of gaining clear ideas of relation, it is sometimes useful to project perception by the aid of mental imagery, and thereby to visualize the invisible in the eye of the mind. So the great aggregate of knowledge is often likened unto a numerical sum, or a reservoir or river fed by many affluents; but a better figure may be found in scientific ideation, and the imponderable body may be pictured as an indefinite nebula or plasma, constantly

growing by accretion and constantly undergoing internal change. This plasma may best be portrayed as for the most part unorganized, with partially or completely organized nuclei and nodes and processes here and there; and there is a certain fitness in conceiving the organized tracts as near the surface where the interactions between external and internal are direct and continuous. In this way the intellectual product of the world may be likened unto a nebula, a cloud gathering in a supersaturated solution, an amœba, or a brain; it may be viewed as a chaos more or less advanced on the way toward cosmos. The image is ideal; it serves merely as an aid in grasping and formulating widespread notions concerning knowledge as an elusive and intangible yet vigorously real and important something; but it is not essential to correct understanding of the main facts in the growth of knowledge.

Knowledge is born of the individual brain fertilized by indirect contact with other brains, and is given unto others with a degree of freedom varying with the disposition of the individual and the perfection of his mechanism for conveying thought —gesture, picture, speech, writing, printing; the growth of knowledge keeps even pace with the acquisition of structures and devices for its expression; and it is a pleasant and significant fact that in general the disposition to dispense knowledge grows strong and active just as the dispensing mechanism improves, though usually lagging a little behind, much as the verdure follows the vernal shower. So the stage of individual knowledge is initial, the stage of common knowledge consequent; so also individual knowledge is barren and unproductive until turned into the general fund to increase and multiply an hundredfold; and so, too, there is progressive growth from the initial stage of individual discovery or invention, through many ill-defined yet successively higher and higher steps, well toward the mature stage of general possession. It is needful to observe that the body of general knowledge can never quite equal the aggregate knowledge possessed by individuals; although stimulated by others, each active individual knows something more than he is able to tell, be he never so free in disposition and facile in expression; and it is the never-ending process of coining and issuing and exchanging the precious product of the cerebral crucible that gives rise to intellectual property-right, and at the same time enriches the great plasma of knowledge and maintains the activity essential to its existence. It follows—and this scientific certitude may be commended to a certain class of socialistic schemers—that the relation between individual knowledge and general knowledge is asymptotic, in that, although the latter constantly approaches, it never can reach the former; indeed, if general knowledge were ever to overtake individual knowledge, through suspension of the laws of intellectuality (undoubtedly immutable as those of vitality), the special province of mental activity would be annihilated and the body of knowledge would sink into quiescence—and, in the intellectual as in the vital, quiescence is death.

As knowledge is produced and given unto others, the freedom of giving is governed by numberless conditions, including the perfection or imperfection of the mechanism for expression, the avidity or indifference of the chosen beneficiaries, and the price fixed by custom; and so it happens that certain discoveries and inventions are directly communicated only to limited groups of individuals, who thereby accumulate special knowledge. In this way cliques and trades and guilds arise and the germ of caste is planted; in this way, too, specialists grow up through the indifference of the masses and their inability to keep pace

with the investigator whose energies are directed along a single line; and eventually, among the most enlightened peoples, special societies are formed for the purpose of fostering or diffusing discovery and invention and thereby rounding out the fecund plasma of human knowledge. It may be noted that special knowledge is nearly as barren and unproductive as individual knowledge, and is soon blasted by the poison of its own egoism, unless the richer part of its substance is guided toward the general mass, to do work as it advances; for it is by no means to be forgotten that the activity of the great body of knowledge culminates in the province or zone of special knowledge, and that herein lies the leaven that leavens the whole.

During recent centuries, and especially during recent decades, specialists engaged in creating knowledge have studied knowledge itself in the hope of learning its nature and origin; and most of these students have become convinced that the basis of real knowledge is found in the facts of the cosmos as revealed by observation or established by experimentation. So the acquisition of knowledge begins with noting particular facts and advances to assembling or grouping these facts, *i. e.*, proceeds from observation to generalization; the second process involves the elimination of the unlike or incongruous, and this leads to discrimination and to the recognition of analogies. In general terms, and somewhat provisionally, it may be said that the analogies so recognized constitute laws of occurrence, which may themselves be generalized, and that the requisite discrimination of analogies leads to the recognition of homologies, or laws of occurrence and sequence combined; the framing of analogies and homologies being legitimate inference, which develops in hypothesis and matures in theory or doctrine to be finally formulated in laws or principles. Knowledge produced in this regular and simple manner is commonly called inductive, though there is always a deductive element coming over from that general intellectual possession by which even the closest specialist is guided in greater or less measure. Now, it is to be noted that acquisition of knowledge is largely spontaneous and unconscious; that apperception lags far behind perception, and that only the adolescent and mature among men and peoples are clearly conscious of their own mental processes, or, indeed, of the existence of mental process; it follows that most of the processes just outlined are ill-recognized or not recognized at all, even by the very makers of knowledge. Moreover, the later steps in intellectual acquisition are commonly the first to be consciously noted, so that the majority of men, even unto the present day, have failed to recognize the true source of real knowledge, and have appealed to all manner of mysterious and extravagant sources for part or all of the intellectual wealth of the world; for while the more complex processes alone were recognized inference was exalted and observation was contemned, subtle imagining ran riot and overshadowed sober reason, and scholastic learning—which the practical makers of progress fortunately ignored or repudiated—grew into a labyrinth of deductions from vain postulates and hazy lucubrations. A new epoch dawned when Bacon formulated the inductive method, though he knew not that the method was old as the human mind and that he but recognized that which all men do, whether consciously or unconsciously. Reviewing the course of intellectual acquisition from observation through generalization and inference and theory unto laws of occurrence and sequence, knowledge may be classified by degree of development, and the simpler and more primitive (whether burdened by assumption or not) may be called empiric,

while the more definitely organized product of special study may be called scientific; and, remembering that the processes of acquiring knowledge are partly unconscious, that portion which is organized unconsciously may be classed as common sense, or sagacity, or the wisdom of experience, while the consciously organized portion may be called science. This summary of the mode of organizing knowledge may be trite, yet it serves to show that the methods of the student of humanity are in no wise different from those pursued in the physical and natural sciences.

In brief, knowledge is ever passing from the individual to the common and from the special to the general, and thereby its quantity is constantly increased and its utility extended; during recent times it is passing also from the empiric to the scientific, and therefore its quality is improved and its beneficence multiplied.

IV.

When the history of the class of knowledge called science is scanned certain tendencies or directions of growth are perceived, and scrutiny shows that these tendencies are in harmony with the course of development of knowledge in general.

1. In general, observation and research begin with the rare or remote and proceed toward the common and the near. This tendency is revealed when the several branches of science are compared. Perhaps the oldest science is Mathematics, which began before history, so that its origin is obscure and cannot certainly be traced to definite objective basis; but the nearly contemporary and closely related science of Astronomy rested on observation of the celestial bodies, though the observation was long clouded by the mysticism of astrology. Then, as wits were sharpened by mathematical research and astronomical observation, exact knowledge was gradually brought down to nearer bodies and under the guidance of everyday observation, and thus the science of Physics arose so gradually and inconspicuously that its early history is lost. Later, shrewd hermits and beldams wrought magic by means of rare substances, and alchemy grew up; and as time passed the manipulations were extended to common things and the ban of secrecy was gradually broken, and so Chemistry arose. These four branches of knowledge concerning the inorganic interacted with mutual benefit, and for several centuries constituted science, in contradistinction from the vast body of vague thought comprised in scholasticism and folk-lore and from the more useful body of commonplace knowledge not yet consciously organized. Still later, attention was attracted by things nearer to mankind in place and character, and first plants and afterward animals were studied systematically, and Botany and Zoology arose; but for a long time the most attractive organisms were the unusual and therefore striking, or specimens brought by travelers from distant lands; indeed, even during the present half century scientific museum administrators are embarassed by the tendency of the collector to neglect the common and collect the unusual in his own locality, and it is only within a generation or two that the ordinary plants and animals supplying mankind with food and clothing and other everyday commodities have been subjected to scientific research. In like manner, the science of Geology began, soon after botany and zoology, with the study of rare minerals and the ancient rocks of remote mountains; gradually the research extended to the nearer hills and valleys and the later formations, and it is only within the present generation that the soil-making deposits on which human life so largely depends have been brought under scientific examination. Last of all, the scientific research beginning

with the stars and passing to minerals and plants and animals, and through the soil on which plants and animals live, reached man himself; yet the studied observation began not so much with fellow-citizens or fellow-subjects bound to the student by ties of consanguinity and affinity as with the abject savage or half-clad barbarian of distant lands; and even to-day, and in the most enlightened nations of the earth, the pictures brought up in most minds by the term Anthropology are those of alien and inferior peoples, or of human curiosities and monstrosities exhibited in midway plaisances, if not in circuses and dime museums. Even in scientific circles—yea, among those ranked as anthropologists—there are many who habitually restrict the term to the purely animal side of Man, and and ignore that broader and nobler side which distinguishes mankind from all other things. So, whether science be viewed in general or detail, it is found that its progress is toward the ego—toward the everyday and commonplace, perhaps, yet ever toward the more important because nearer, the more useful because the commoner; and the more nearly it approaches the more clearly it is seen that science dignifies both student and object of study—that exact knowledge, with Midas touch, turns dross to gold.

2. In general, research begins with the abnormal and proceeds toward the normal. Judging from the habits of present-day barbarians among whom the tempest is studied and the zephyr ignored, the comet remembered and the planet forgotten, the pre-Chaldean astronomers based their first celestial observations on the erratic wanderers rather than the orderly travelers of the sky; and in all ages prodigies—the bizarre and ill-formed, the gigantic and dwarfish—have been the first to catch and the longest to hold attention, among casual observers and specialists alike. This tendency toward noting the abnormal, like that of regarding the rare rather than the common, is the easily besetting sin of the touring naturalist and local museum collector, the joy of the unscientific and the despair of the scientific among museum administrators. Clearly seen in geology and zoology and botany as the vestige of a primitive past, this tendency to perceive only the abnormal is still strong—indeed almost dominant—in the younger science of anthropology; to-day distorted or wounded or cachectic skulls from the ancient ossuaries of Africa or the huacals of Peru are esteemed far above normal crania of a normal people who have by normal activities aided in making civilization and ennobling the world; to-day the platycnemic tibia and perforate humerus of questionable significance are exalted above the normal members occupied in the march of progress and the conquest of lower nature; to-day there are a flourishing sub-science called criminology and a fantastic fad of extolling and magnifying degeneracy, while the upright in mind and the sound in body are relatively neglected; yet this apparently morbid taste but reflects a tendency of the human mind, and is the promise of better things when the intellect awakened by the abnormal acquires the power of appreciating the normal. Unremembered milleniums of mystical shamanism were required to produce pathology and therapeutics, and centuries of pathology were needed to produce sound physiology and etiology, and in like manner there were generations of mystical and irrational psychomancy before students were able to recognize a basis for the modern and most promising science of psychology. It smacks of the paradox to say that the beginning with the abnormal is the normal course in the making of science; yet the history of each and all of the sciences shows that observation on the abnormal has always led attention to the normal, just as observation on the remote

has ever guided attention toward the near; and it is but natural that the youngest of the sciences should yet retain vestiges of undue magnification of the abnormal.

3. In general, scientific determination proceeds from the qualitative to the quantitative. The tendency is displayed by every branch of science, and so conspicuously that it may be deemed characteristic. It is in accordance with this tendency that estimate precedes weighing and reconnaissance goes before surveying; and it is under the same tendency that scientific progress involves constantly-increasing refinement in observation and ever-growing accuracy in definition.

4. In general, scientific interpretation proceeds from the formal to the physical,* from the material or the inert or the static to the dynamic. The positions and movements of the moon and planets were determined with fair accuracy before Newton discovered that the paths of these and all other celestial bodies are fixed by gravity; when this discovery afforded the means for determining position and movement with incomparably greater accuracy. The physical and chemical effects of heat were recognized for generations, and were ascribed to the hypothetic element phlogiston or the imaginary fluid caloric long before Juole and others found it to be merely a manifestation of molecular motion; whereupon physics and chemistry were revolutionized and the forces of nature were gradually harnessed many times more effectively than before.

The ancients recognized vitality and ascribed it usually to a material something joined to the matter of the body. Some twenty-four centuries ago sagacious Heraclitus conceived life as a universal fire, and less than five centuries ago Paracelsus, and after him van Helmont, wrote of the anima mundi, or archeus, having in mind a vaguely imponderable thing akin to the so-called astral body which votaries of an oriental belief imagine themselves able to materialize out of the depths of transcendental revery; two centuries ago Hoffmann and other anatomists spoke habitually of the vital fluid as contemporary physicists of of phlogiston, and within a hundred years leading physiologists, like Hunter, thought and wrote of a 'diffused vital material;' less than a quarter-century ago Barker was deemed bold unto recklessness for undertaking to correlate vital and physical forces,* and many heads were shaken doubtfully when, in his presidential address before the American Association at Boston in 1880, the same brilliant experimentalist argued from the applications of Mosso's plethysmograph that mental force also may be weighed and measured, so that it must be regarded as inter-convertible with other forms of energy;† yet half a generation of organic chemistry and physics has established these revolutionary propositions beyond peradventure, and introduced a new era of biologic research.

The tendency toward dynamic interpretation is well shown, too, in geology. In the infancy of the science, formations and the extinction of faunas were ascribed to extra-natural cataclysms, the opening of valleys and the shaping of hills to ill-conceived or inconceivable catastrophes; with Lyell—a personal associate of scientific men now living—came the doctrine of uniformism, under which it is recognized that existing rains and rivers and silt-distributing waves are competent to produce the

*As defined by Le Conte in a notable article 'On the Structure and Origin of Mountains,' *American Journal of Science*, third series, Vol. XVI., 1878, page 107.

*'The Correlation of Vital and Physical Forces,' University Series, Number 2 (Van Nostrand), 1875.

†Proceedings of the American Association for the Advancement of Science, Volume XXIX., 1881, page 12 *et sequentia.*

land-forms and formations of the earth, provided time enough be allowed them; the present generation of geologists, beginning with Powell and including two score others, have scanned the pages of the Great Stone Book, so well laid open by Colorado and other rivers, and have learned to read earth-history from land-forms as well as formations, and have shown that at least a portion of those earth-crust movements which were sheer mystery to Lyell result from the slow transfer of rock-matter by the action of running water. As interpretation grew definite and the mystery of earth-making dissolved, the classification gradually changed from chiefly material or static to chiefly dynamic; for a time the formations were classified by the processes of accumulation; and now the foremost geologists classify earth-science primarily by the great agencies of earth-making.

In anthropology interpretation has not yet grown definite and there are nearly as many modes of interpreting as there are men to interpret, yet even in the short and complex history of this youngest of the sciences the general tendency appears; for the earlier classifications were based on bodily or somatic features, while the more advanced among current classifications rest either on collective attributes or on the activities of the human groups—*i. e.*, the older classifications indicate what men are, the newer indicate what men do. Only half a generation past was it definitively suggested that human mentality is a form of energy, but already the testimony of the plethysmograph has been corroborated in so many ways and so widely extended that most scientific students of mental phenomena assume, either explicitly or implicitly, the essentially physical character of intellectual action; and in this writing it is assumed that intellectual energy is paramount in that it is able to control other forms of energy and make conquest of nature through invention and construction, and the faculties and works of man are classified and interpreted accordingly.

So in astronomy and physics and chemistry, and equally in biology and geology, the progress of science may be measured by the ever-increasing recognition of the dynamic aspect of phenomena, of the physical forces by which the material things are moved; with the recognition of inherent energy or motion, observation progresses from the merely qualitative to the quantitative, and constantly increases in refinement; and in view of this progress in other sciences it can hardly be regarded as premature to attempt the extension of quantitative measure and dynamic interpretation to that side of anthropology which deals with the purely human attributes.

5. In general, scientific interpretation progresses from the stationary to the sequential; for the idea of action engenders the idea of succession. The Chaldean shepherd, the Egyptian soothsayer and the Peruvian priest, like the earlier oriental astrologer, probably first took note of the celestial bodies as striking features of the cosmos, and later observed their rhythmic procession with such care that cycles were established and eclipses and other prodigies were foretold long before the true structure of the solar system was understood. These ancient observations and interpretations must have implanted that idea of the uniformity of nature which has borne so splendid fruit during the present century; the budding notion found poetic expression in pleasing fancies of firmaments of crystal and the music of the spheres; yet it was not until the germinal idea was fertilized by the Newtonian law that the marvelous measure of celestial rhythm came to be known. Led by the planless experiments of daily toil, the mechanic—forerunner of the physicist—was the next to lay hold on the notion of uniform succession; it grew

with the centuries and spread into the neighboring domain of chemistry, where it vitalized the dynamic interpretation of chemic union and aided in producing Avogadro's law, which, according to Cooke, 'holds the same place in chemistry that the law of gravitation does in astronomy '* and forms the basis of what has justly been called the New Chemistry. This law, like all others in science, afforded a means of prevision, or of presaging the unknown in terms of the known, and thus of testing its own validity; and as test followed test the idea of orderly succession grew until, with the aid of refined observation and the guidance of special experiment, it matured in the doctrine of the persistence of motion, the keynote of modern science. Here was a vantage point from which the astronomer was enabled to study the celestial bodies, especially our own sun, not merely as masses, but as chemical and physical assemblages; and so arose the line of research sometimes called celestial physics, but defined and dignified by Langley as the New Astronomy,† which has already afforded a means of analyzing the constituents and measuring the movements of several among the myriads of other suns than ours. True, each of these strides in the advance of physical science represents progressive appreciation of cosmical forces; yet still more fully do they represent progress in recognizing orderly sequence and causal succession in the movements of molar and molecular bodies.

Borrowing from physical science trenchant ideas concerning force and succession, even the earlier biologists analyzed the mechanism of living things and slowly stripped away the primitive panoply of mystery or divinity in which the infantile imagination, whether of men or races, has always enveiled vitality. Lamarck was one of the first to extend the idea of orderly succession to organisms, and, although his special hypothesis of development has fallen into abeyance, it has features which anthropologists do well to remember; then came patient Darwin and doughty Huxley and studious Spencer with the definite doctrine of organic evolution, which spread from man to man and from land to land, producing the greatest and quickest intellectual revolution in the history of the world. Albeit revolutionary, the Darwinian doctrine was but the biotic complement of the physical doctrine of the persistence of motion, and the two doctrines are twin buttresses on which the symmetric structure of modern science is supported. Through the latter doctrine the world and the things thereof were transfigured in a new beauty and perfection, the universe was invested with a new glory, and the narrow notion of breaks in the uniform course of nature by special fiat lost hold on the scientific mind forever.

It chanced that while the ferment of evolution was still fresh a trio of American geologists (Powell, followed by Gilbert and Dutton) entered the inspiring region traversed by Colorado Canyon, and before their work was done the germ of geomorphy, or the New Geology, was planted. It was realized more clearly than ever before that the hills are not everlasting but everchanging, and that the features of every landscape tell an eloquent tale of continental evolution in which competent cause and commensurate effect follow ever in ceaseless succession through the eons of earth-making. The task of the geologist is not ended, indeed is only well begun; yet here as in other sciences the reign of law is realized, and the day of appeal to chance is past.

When Huxley sought 'Man's Place in Nature,'* and still more when Darwin

† 'The New Astronomy,' 1888, chapter 1.

* First publication in 1863.

traced 'The Descent of Man,'* the fruitful idea of the uniformity of nature was pushed into the domain of anthropology, and has now guided for a generation those branches of the science which deal with the animal side of Man; it is true that the rhythmic sequence of cause and effect has hardly been extended so far as to cover the delicate and elusive attribute of humanity, but this extension is the motive of many investigators, the aim of the present writing. Already the broad realm of humanity is fairly defined, and the distinctive form of developmental succession proper to this realm is fairly outlined, so that the distinctness of the science of human attributes has been made clear; for while stellar and molecular and organic development are evolutionary in that the main tendency of change is toward differentiation, the development of humanity is involuntary in that the main tendencies are toward integration and combination. Conformably to the fundamental facts of the great realms of nature the earlier sciences are largely, perhaps chiefly, analytic, while the science of humanity is largely, perhaps chiefly, synthetic; and its votaries seem to find reason for figuring it as the central dome crowning and conjoining the separate columns in the ideal pantheon of science. If the confidence of the votaries is just, the youngest of the sciences may be expected to repay with interest all that it received from the several branches of knowledge whence it sprang; already, indeed, it has thrown light on the course of organic development through researches on the human body, and has begun to guide the acquisition of knowledge through researches on the human brain and its functions; already it is contributing to the physical sciences, *e. g.*, through the refreshing Powellian doctrine of conservation, or of common persistence of motion and matter in the ultimate particle, whereby ideas concerning the mechanism of the universe would seem to be immeasurably simplified and extended; and there are other ways in which the youngest science is daily contributing to the stock of definite knowledge; their name is legion.

* The first edition of this notable work appeared in 1871.

So it is that science has always progressed from the rare to the common, from the remote to the near, from the abnormal to the normal, from the merely qualitative to the quantitative, from the merely material aspect to the physical aspect, from the primitive faith in fixity to living realization of causal succession. At first sight this progress may seem puzzling, even paradoxical; yet the general course is but an expression of the order of intellectual operations pursued in scientific research. The first step is observation, which is easy when the objects observed are isolated or distinct, increasingly difficult as the objects increase in number and similarity; the second step is generalization, which is relatively easy when the objects examined are few, relatively difficult when they are many; while the ancillary process of discrimination of the incongruous likewise grows laborious with the multiplication of objects and similarities. Accordingly it is easy to study the rare, the remote and the abnormal, and as faculty is strengthened by exercise, it gradually becomes easy to progress toward the common, the near and the normal. So, also, qualitative determination is easy, quantitative determination difficult; indeed, exact quantitative work is impossible without careful training, as numberless surveyors and teachers can testify. In like manner, interpretation in terms of the material, coupled with appeal to the supernatural when obstacles are encountered, is relatively easy and characteristic of the indolent or immature mind, while the firm grasp of

analogy and homology, and the clear recognition of energy and sequence, require both native capacity and systematic training. Accordingly, scientific interpretation in terms of action and succession is the end of mental effort and may be regarded as the highest expression of intellectuality. This correspondence between the method of research and the history of science throughout the centuries amply attests the excellence of the method. Yet it is not to be forgotten that just as intellectual grasp strengthens, so interpretation is simplified, partly through the elimination of that question-begging mysticism which pervades all primitive philosophies, partly through clearer arrangement of facts and relations; and as interpretation grows simple three especially noteworthy effects follow: (1) Each step in interpretation makes the later steps easier; (2) as the labor lightens, more energy is left for the next task, and the mind of the student pushes into new fields of study and from time to time organizes new branches of inquiry; and (3) with each extension of inquiry mental faculty is stimulated and strengthened. These tendencies are clearly indicated by the birth and growth of new sciences recorded in the history of research; beginning with the celestial bodies it has extended to mechanical bodies, vegetals, animals, the earth itself, then to the human body, individual and collective; and now it is reaching out toward the special attributes of mankind, the things nearest to human welfare and happiness.

V.

The domain of Anthropology is vast, and, partly by reason of its very magnitude, is sometimes deemed indefinite; yet in the light of the history of science in general its limits and subdivisions may easily be outlined.

History and analogy combine to show that the study of Man began with wounds and diseases and grew into surgery and medicine, which were at first thaumaturgic, but gradually became rational or scientific;* and in this way definite knowledge of the human body gradually accumulated and Anatomy and Physiology, with various ancillary sciences and sub-sciences, took form and function. Meantime the organs of the human body were compared and identified with those of beasts and birds (which were long the better known), and comparative anatomy was established; but it was not until observation and generalization were fertilized by scientific zoology that the study of structures in their functional aspect took shape in Morphology. Under the influence of humanitarian therapy and the unprecedented stimulus of the Darwinian doctrine of development the investigations of the last century, and particularly of the last quarter-century, have extended from structures to functions, and these, through the fruitful science of Embryology, to human ontogeny and phylogeny—to the individual and generic evolution of Man considered as an animate organism. Accordingly there are several branches of science which deal alike with the human organism and the various other animal and even vegetal organisms of the great vital series in which Man is usually, though not invariably, considered the culminating and crowning form. Here anthropology and biology blend; but it is convenient and desirable to distinguish that division of the Science of Man which deals with the organic features of the order Bimana, and this science or subscience is frequently called *Somatology*. Although the oldest and the simplest among the divisions of anthropologic science Soma-

*The genesis and development of surgery, and incidentally of medicine, are discussed in a memoir on 'Primitive Trephining in Peru,' Sixteenth Annual Report of the Bureau of American Ethnology, 1897, especially on pages 19 and 72.

tology comprises various special branches of knowledge commonly classed as sciences, including Pathology, Physiology, Etiology, etc., representing the specific methods and purposes of particular classes of investigation.

The early books and maps of civilized nations show that explorers and pioneers were profoundly impressed by the far-away peoples encountered in their wanderings; there are not only accounts but pictures of headless men with faces in their chests, of cyclops with single eyes set skyward, and of other impossible monstrosities in human semblance; even since zoology became fairly definite, accounts of ten-foot giants in Patagonia and three-foot pygmies in Central Africa and other lands remote or hidden have gained currency and credence. As exploration continued, the unconscionable extravagancies of vision were gradually corrected, and the explorers came to see alien races in proper form and something like proper stature; yet the interest in the stranger peoples remained unabated and led to systematic observation and record. Borrowing methods from biology, the observers or their interpreters sought to classify the men of different continents and provinces and islands by somatic characters —by stature, color of skin, color and texture of hair, color and attitude of eyes, form of feature, form and size of skull, peculiarities of long bones, etc.; and, as the researches became definite and fruitful, they were combined in a science of races called *Ethnology*. This science has much in common with biology, and is a direct outgrowth from that group of sciences pertaining to the human body combined under the term Somatology.

After centuries of unscientific and unsuccessful search for the seat of the soul through baseless deduction and blind introspection, certain thinkers began to profit by contemporary researches in anatomy and physiology; and as eye and mind were trained—even as the eye and mind of the traveler were trained not to make monstrosities out of unfamiliar races—the form and function of the nervous system were gradually recognized, and the dominance of the brain was finally established. Only within a generation or two has the brain been investigated in a scientific way and with due appreciation of the importance of that marvelous structure preformed in the articulates, potentialized throughout the long line of vertebrates, and perfected in the ultimate mammalian form of the genus Homo; yet during the present quarter-century the research has been organized in a science already cultivated in many lands and taught in most of the leading universities. The earlier promoters of this science approached the subject haltingly from the speculative or deductive side, and perhaps for this reason the science is named not so much from the organ itself as from its product, *Psychology*. This modern science is not to be confounded with certain fantastic notions sometimes foisted under the same designation which do little more than obstruct progress; the parent stock of the science was indeed speculative—as is most knowledge in the beginning—but so soon as the graft of somatology was affixed it became fruitful. It is to be noted that while Somatology is essentially biotic, and Ethnology is biotic in so far as it rests on bodily features, Psychology pushes beyond the domain of biology proper, partly in that the human brain owes its perfection of development to the essentially human attributes, partly in that the science, as commonly defined, embraces both brain and mind—both organ and product.

So there are three well-established and and widely recognized sciences whose object-matter is Man considered as an organism; by some students, especially those of past decades, they are held to constitute

the whole of anthropology; by others they are combined as physical anthropology and regarded as including only the animal side of man, but excluding nearly the whole of the essentially human side—nearly, but not quite, the whole, since the field of psychology is common ground. This is the view of several modern anthropologists, and is that held in this writing.

VI.

Passing from that portion of the domain of anthropology which deals with man as an animate genus, there is found another and still broader portion occupied by that which man does as a sentient, volitient and intelligent being; it is true that this portion of the domain is less definite than the other, yet, in the light of intellectual progress, its limits and subdivisions also may be outlined, albeit in some measure provisionally.

The early explorers who came home laden with travelers' tales sometimes brought also more tangible cargo in the form of strange wares; and so the handiwork of the world gradually came under the observation of students, and in time museums were built largely to accommodate the constantly increasing collections of primitive and alien arts. Meantime observant persons in many countries were attracted by relics of archaic culture in the form of implements, weapons, ornaments, apparel and habitations, as well as burial places sometimes containing the bones of the ancient artisans, and these, too, were collected, and museums were built to accommodate them in connection with the artificial material gathered among the living peoples of distant lands. As collectors and collections multiplied, the work was organized; and, although the initial stimulus came from observation in remote countries, the interest grew inward—as is the way of advancing knowledge—and the local research for the rare relics of past ages was the first to receive name and character as the science of Archæology. As observations multiplied, resemblances were found between the culture-products of remote times and remote places; the arts of primitive peoples were found to vary in a manner corresponding more or less closely to race, and thereby ethnic research gained new impetus and served in turn to guide research in the prehistoric. So archæology and ethnology became mutually helpful and grew apace and came to be intimately assosociated in most minds, despite the fact that the one is concerned primarily with what man is, the other with what man does; and in some circles these branches of inquiry came to be regarded as constituting the whole of anthropology.

At first the products of ancient and alien handiwork were accepted at their token value, much like the chemic elements before Avogadro, the planetary movements before Newton, our sun and others before the doctrine of the persistence of motion, the organic species before Darwin; but within a generation or two it has come to be realized that they possess an innate value as exponents of intellectual activity —as medals of human creation collectively attesting the birth and growth of discovery and invention, design and motive, and all other human faculties. Perhaps the time has not come for defining this stage in the progress of anthropology; it may be that the transition is not yet complete, or that the relations are too complex for easy grasp; yet it seems clear that when the anthropologist first saw in the implement of shell or stone an index to the mental operations of the implement-maker hardly less definite than the written page to the thought of the writer, the Science of Man rose to a higher plane with a bound comparable to those marking great epochs in the development of the other sciences.

Now, in science, each advance gives a new standpoint from which a broader view may be gained; and with the recognition of what may be called the dynamic aspect of artificial objects the way was prepared for further progress. It was soon perceived that the simplest devices are supplements to or substitutes for bodily organs—that the knife of shell or tooth or stone is a supplement to teeth and nails; that the hammer-stone multiplies the efficiency of blows, and that the missile is equivalent to an indefinite prolongation of reach; and accordingly it was realized that, in so far as he is a maker and user of implements and weapons, even the lowest savage rises above the plane of purely animal life. It was next perceived that even the simplest devices react on the organism in various ways. The substitution of the shell knife for nails and teeth diminishes the exercise and hence the vigor of these organs and removes them from the category of characters subject to development through the survival of the fittest in the strife for existence, so that in so far as he employs devices in lieu of organs the savage passes beyond the realm of organic development by natural selection; at the same time the exercise of making and using artificial devices in lieu of natural organs tends to develop distinctively intellectual or cerebral characters, so that the effect of competition in the use of devices is not only to remove Man from the realm of the biotic, but to set him on a new course in a different realm—the realm of the artificial or essentially human. As the view of the artificial continued to broaden it was perceived that while the simpler devices may appertain to individuals they are not integral parts of the individual, like the organs which they supplement, but may and do pass from hand to hand and from group to group; also that the use of a device by one person prompts others to acquire and use similar devices, which they are able to do immediately through mere exercise of individual volition (rather than slowly through generations of natural selection), so that each discovery or invention is at once the germ of a line of devices and a stimulus to intellectual power; and thus it was recognized that there is a strong communal tendency in the realm of the artificial—that the development of devices tends toward interchange and cooperation, yet ever of such sort as to augment intellectual power and elevate the human above the sub-human.

In the light of the dynamic interpretation of devices it is easy to perceive the trend of superorganic succession, or development of the artificial, and to contrast it with the course of biotic evolution. The substance or substratum of the latter is living matter; that of the former any matter, living or dead, with which man chooses to deal; the mode of this is slow elimination of the unfit and unpremeditated survival of the fit, the method of that is immediate imitation and designed improvement of the ingenious; the tendency of biotic evolution is toward organic differentiation, that of artificial development mainly toward organic persistence with endless multiplication and integration of devices; the effect of the one is individual or egoistic, that of the other communal and altruistic. With the recognition of the dynamic and successional aspects of artificial devices, anthropology gained a new significance; for to its objects-matter in the form of the human body and human races and the human brain there was added the whole series of artificial devices and the exceeding potent intellectual activities which these devices represent; and this addition is the basis of what is here styled the Science of Humanity.*

* The enlargement of the domain of Anthropology as here set forth is regarded as marking the most important epoch in the development of this science, one of the most important in the development

VII.

When artificial devices were interpreted in terms of activities a new classification of human handiwork arose. At the same time the activities themselves became objects of research, which soon passed beyond the collections and extended to the multifarious material devices in daily use among living peoples in the various stages of civilization from savagery to enlightenment; still later the research was extended to the intellectual or non-material devices which preeminently distinguish mankind, such as law and letters and learning in their numberless aspects. The study of the activities is now sufficiently advanced to indicate, at least provisionally, their relations among each other and to the merely organic processes; they may be arranged in the order of their affinity with the vital.

The primary activities of mankind are connected with more or less spontaneous sensations of pleasurable character. They arise and expand in fairly definite order; among known primitive peoples they appeal chiefly to the senses, and among more advanced peoples they appeal largely to the emotions and the purely intellectual faculties; they root in sports, games and decorations, and mature in the fine arts of painting, sculpture, the drama, poesy and music, *i. e.*, they constitute the esthetics. The artificial devices growing out of these activities go far toward filling those museums of the world devoted to archaic and ethnic material, and nearly a third part of current anthropologic literature is devoted to this class of objects and the activities which they represent. The activities and activital products form the object-matter of a broad and fruitful field of inquiry known of late as *Esthetology*.

2. Intimately connected with the primary activities, and also originating in spontaneous vital processes, though becoming dominant only by organization through exercise and volition, there are other activities tending toward the maintenance of physical welfare. From a simple beginning in occupations akin to those of the beasts, they arise and expand with each step in cultural advancement from savagery to enlightenment; at first confined to food-getting, they extend also to the making of apparel, the building of habitations, and eventually to the supply of intellectual demands, *i. e.*, they constitute the industries of common parlance. The material devices growing out of the industrial activities have enriched anthropologic museums almost equally with those growing out of esthetic activities, and probably a fourth part of the current literature of anthropology is devoted to them and the activities by which they are produced. Together they form the object-matter of a large and rich science commonly called *Technology*.

It is to be noted that the greater part of the material investigated by the archæologist pertains also to the fields of Esthetology and Technology, though these are far broader in that they extend not only to a greater variety of activital products, but to the activities themselves. It may also be noted that both esthetics and industries, originating as they do in vital processes, are primarily individual, though they become collective partly through combination with higher activities; while the higher activities of the series are primarily collective. It is noteworthy, too, that the two lower classes of essentially human activities rest on a material basis and are represented primarily by material devices, while the

of science in general. Several investigators have contributed to it; perhaps the earliest, one of the most voluminous, and certainly the most original, of these contributors is J. W. Powell, whose preliminary writings have appeared in a large number of addresses, official reports and minor papers, though his final conclusions are not yet published.

activities of higher planes rise above the material in their essential character and are only incidentally represented by material devices.

3. The activities of the third class are connected with collective relations; and, since they grow out of consanguinity or family relation, they may be said to have a biotic germ. In general, the products of these activities originate as customs which grade into regulations and later into laws, and are perpetuated in tribal, national and other institutions. The activities and their products are most intimately connected with, and indeed form the chief basis of, cultural progress. In the first culture stage, corresponding to what is commonly called savagery, the collective or social relation is based on kinship traced in the maternal line; in the stage commonly called barbarism, social relation rests on kinship traced through the paternal line, these stages forming tribal society. In the third stage the social organization passes from patriarchy, through feudalism, or an equivalent intermediate condition not yet formulated, to that stage of individual property-right in lands and goods which is commonly called civilization; and men are now passing into the stage characterized by intellectual property-right which is commonly called enlightenment, the organization in the last two stages being essentially non-consanguineal and constituting what is sometimes called national society. The several activities and activital products belonging to this class form the object-matter of a fecund science commonly called *Sociology*, though the day of final agreement concerning the definition of the term is not yet.

4. In some measure the activities of the fourth class are an outgrowth of those of the third, since, although essentially superorganic, they may be regarded as a means of establishing and maintaining relation; they comprise expression, pantomimic, oral and graphic. Like the other activities, they arise and expand in a certain order; beginning with what is somewhat incongruously called gesture-speech and with rudely articulate language, they mature in oratory and literature; and it is significant that the lines of development, so far as ascertained, run counter to those of biotic evolution in that they are almost wholly convergent instead of divergent; so that these activities pertain, in every essential respect, to the superorganic realm of humanity. The principal activities are speech and writing; the tangible products are legend and literature; but the rich and ever-growing content of these products is knowledge. The activities of expression and their products are commonly combined as the object-matter of another science frequently called *Philology*, though in this case, too, there is diversity in definition, and also in designation.

5. There remains a class of elusive and protean, yet immeasurably potent, activities which come so near the ego and are so hard to grasp and difficult to convey that it would seem almost hopeless to attempt to define them; they are the essentially intellectual activities which form the motive and burden of expression, and their products comprise beliefs, opinions, knowledge, wisdom and all other purely intellectual possessions. These activities also arise in a definite order, which is set forth incidentally in earlier paragraphs; and by most systematic thinkers they are considered to mature in science. The activities and their products are so obscure and so diverse that they have not been combined and named in the vernacular; yet they are by some students regarded as the object-matter of one of the broadest of the special sciences, *Sophiology*.*

So there are five classes of essentially human activities and activital products, each

*Sixteenth Annual Report of the Bureau of American Ethnology, 1897, page xviii.

so rich in phenomena and principles and so far distinct from all other classes of things as to constitute an adequate basis for a science; they are the fine arts, or esthetics, giving basis for Esthetology; industries, forming the object-matter of Technology; organizations or institutions, affording foundation for Sociology; language and literature with their science of Philology; and the great plasma of knowledge, forming the ill-defined but all-important object-matter of Sophiology. The five fields of research pertain primarily to Man and thus represent Anthropology; yet even casual survey of their extent and character renders it evident that they pertain not at all to the animal side of Man, but wholly to that side which intellectual Man alone possesses; they are five sciences of Humanity. Partly to distinguish them from the three distinct branches of knowledge concerning animal man, partly to fix their place in the body of knowledge, they have recently been combined under the term *Demonomy*;* and this system of organized knowledge concerning wholly human things may fitly be designated the greater Science of Humanity.

VIII.

As knowledge arises it is applied to the promotion of happiness and welfare; this has been true of unorganized and unconsciously organized knowledge throughout the history of mankind, and is especially true of definitely organized knowledge which thereby becomes applied science. Now knowledge concerning the human activities, even while unconscious or half conscious only, reacts upon and shapes the activities in such manner as constantly to increase their potency. Some of the ways in which the science of humanity stimulates and strengthens human activities are especially noteworthy.

* Fifteenth Annual Report of the Bureau of Ethnology, 1897, page xix.

1. While the great domain of Anthropology is divisible into an animal side comprising three broad sciences and a human side made up of five still broader fields of research, other classifications are possible, and indeed of special utility when directed toward the practical application of the science to every day affairs; for any assemblage of facts and relations may be classified in as many ways as there are purposes of classification. Experience shows that there is a peculiar advantage in classifying certain sciences by method of research rather than by the objects under investigation. Classified in this way, anthropology comprises: (1) demography, *i. e.*, the enumeration and description of men, activital products, etc.; (2) human geography (or anthropogeography), dealing with the geographic distribution of peoples and their artifacts; (3) political economy, which is concerned primarily with applied social forces and their products; (4) history, which deals with the rise and fall of peoples and nations; (5) philosophy, which scrutinizes materials and forces and sequences, and seeks the causes of growth and decadence among human things. This classification traverses the same domain as the more general one, and serves to bring out the same facts and relations in somewhat different light, *i. e.*, it is artificial rather than natural, technical rather than logical, subjective rather than objective, directive rather than creative; in brief, it pertains to applications rather than original research. For certain purposes it is desirable to combine the classifications and define special fields of inquiry by the coincidence between the two, as has recently been done happily by Giddings* and others; for the lines of thought represented in the two systems are strengthened by interaction; the one represents science, while the other may stand for statecraft or

* 'The Principles of Sociology,' 1896, page 49.

learning, and the two combine to advance mankind in knowledge and power.

2. At the outset the science of ethnology was closely affiliated with zoology, representing indeed little more than the concentration of biologic inquiry on a single order of animate organisms; but with the recognition of human activities this science was raised to a new plane. The applications of demonomy in the classification of peoples and races are many and sweeping; already the natives of the western hemisphere are classified primarily by language and incidentally by other demotic features rather than by any or all biotic characters; already the great stages in human progress from savagery to enlightenment are seriated in terms of social organization in lieu of those of the bodily features with which the biologist is wont to deal; already the present-day ethnologist gives first thought to the arts, industries, institutions, languages and ideas of the races rather than to any or all of those individual features comprised in stature and form and color; already, indeed, the recognition of human activities and the course of human development has served to revolutionize the science of races no less completely than the older sciences were revolutionized by recognition of force and sequence; and just as the New Astronomy, the New Chemistry and the New Geology are distinguished, so it is meet to distinguish a New Ethnology as a science of artificially organized groups rather than of mere upright animals.

3. With the rise of knowledge concerning activities, it was perceived that the primary function and ultimate end of devices have always been to extend and increase human power, to enable man to control plants and subjugate animals, and to evade or utilize sun and storm, *i. e.*, to make conquest of lower nature; accordingly it was recognized that, while the human characters reflect environment measurably, as the purely biotic characters do fully, it is the essential tendency and character of man to control, rather than to be controlled by, his environment. This human power did not spring into being full-fledged—indeed, science knows no Minervan birth—but grew up slowly through the exercise and gradual strengthening of volition and the evolution of design; so primitive peoples are partially controlled by their environment, while the control diminishes with successive culture stages up to that of enlightened man who dominates by multifarious devices nearly every physical force. Examination of the successive stages in emancipation from environment brings to light many significant relations; thus it is found that when two or more primitive peoples of similar culture are subjected to similar conditions of environment their minds respond in similar ways, so that similar devices are discovered or invented; and recognition of this law of human progress has served to correct some of the most persistent misapprehensions by which anthropology, like all other sciences in their infancy, has been burdened. At the same time the recognition of progressively increasing conquest over the inorganic, and the organic merely, has served to define and dignify man's estate at the head of all nature.

4. Although certain human characters and characteristics were already under investigation, it can hardly be said that mankind in general came into the domain of scientific inquiry until the Darwinian doctrine of evolution was accepted; accordingly, anthropologists at first regarded Man as subject to the law of organic development through the survival of the fittest. Then came the recognition of activital development in contradistinction from organic development, and the pendulum of opinion swung back so far as the most modern anthropologists implicitly assumed the human

form—the form of the order Bimana, genus *Homo*, and species *sapiens*—to be fixed and final. It now appears that the pendulum swung too far; for a long series of highly significant yet but half appreciative observations indicate that, just as the human mind dominates the materials and forces of lower nature, so may it measurably control and fashion the organism in which it is embodied; already hygiene and gymnastics have improved unnumbered physiques and lengthened the days of thousands; already leading educational institutions maintain physical departments in which they undertake so to shape and strengthen the limbs and lungs and even the heart and bone of the matriculate that he may be graduated sound in body as strong in mind; yet these indications would seem only to point the way of progress, and promise still better things in human development as later generations rise.

5. The most elusive attributes of humanity are those manifested in conduct and feeling and thought; yet, paradoxically, it was these obscure products of intellectual activity that men first sought to guide and control, for in every generation, in each stage of culture from the lowest savagery to the highest enlightenment, parents have essayed to train their children, while first the tribal leaders and later the sages and statesmen have semi-consciously or in full consciousness striven ceaselessly to shape the minds of the masses. So education, or the voluntary control of individual mentality for the common good, has affected profoundly the entire course of human development, and has served ever to widen the chasm separating man from the beasts. In the earlier stages of culture, as indicated by the customs of savages still living, education was limited to the lowly esthetic and industrial activity of the prime; for the primitive thinker ascribes motive, complex feeling, and all but the simplest actions to ill-conceived extraneous potencies against which it were bootless to strive. In higher savagery and in barbarism the sphere of education extended to those features of conduct involved in the maintenance of tribal relations, and was effected partly by means of habitual appeal to the extraneous potencies which were gradually crystallized in mythic systems themselves arising in a certain order determined partly by educational practice; for in much of savagery and in all of barbarism the sources of sentiment and motive are sought outside the individual and largely beyond the realm of the real. With the birth of civilization education extended to feeling and thought, partly through appeal to ideal potencies, and there was a tendency to exalt the esthetic and neglect the industrial; and certain educational systems rose so high into the supernal or passed so far into the metaphysical as to lose sight alike of individual conduct and the sources of real knowledge. In modern enlightenment—especially in America—the methods and purposes of training are shaped by science, and, despite the struggle of the scholastics, education is becoming revolutionized. With the recognition of an actual universe knowable through sense and reason, training becomes definite in plan and useful in purpose; with the recognition of cerebral function and of the influence of exercise in developing the brain, the scientific psychologists of the present decade have gone far in erecting a new platform for pedagogy; and with the recognition of the relations among the activities and the activital products of man, the normal course of intellectual development would appear to have been made clear; for it seems manifest that just as observation begins with the simple and proceeds toward the complex, and just as activity begins with the spontaneous and passes into the volitional, so individual and collective mentality must arise in simple and perhaps

spontaneous action, to grow, through habit, into sentiment, and to mature, through unconscious or conscious thought, in definite motive. It is heterodox, perhaps in more senses than one, to affirm that motive—the noblest character of humanity—buds in spontaneous action, blossoms in subconscious habit, and attains fruition in the highest intellectual activity, whether unconscious or conscious, of which the individual or group is capable; certainly the affirmation represents complete inversion of a notion prevalent in savagery, dominant in barbarism, and gradually weakening through civilization; yet it is sustained by all that is known of the processes of acquiring knowledge, by the history of the growth of knowledge in general, and, indeed, by nearly all applied statecraft and most applied priestcraft throughout human history. The recognition of the genesis and antecedents of motive must afford a vantage point for a clearer survey of the vast field of human emotion, affection, passion, aspiration, disposition; and, at the same time, it cannot fail to give a key-note for improved education—for the still more complete control of mind.

These are but a few of the many ways* in which the great science based on human activities tends to bring order out of that vast chaos of action and thought which has so long resisted analysis and synthesis—that last citadel of the unknown.

IX.

Hitherto Humanity has been the theme of poesy and romance rather than of sober science. All men have perceived that their kind possess attributes distinguishing them from the rocks and plants and beasts of lower nature, yet for the most part these attributes were either ignored or transfigured into a dazzling halo which defied analysis none the less by reason of its subjective character; even to-day and in the most enlightened circles of the most enlightened nations there are few willing to consider, and content to consider dispassionately, the purely human attributes; but to these few the chaos of industries and ideals, of emotions and passions, of conduct and motive, and of all other things human, falls into a simple order nearly as definite as the order recognized in each of the older sciences—the order of human activities and activital products.

* One of these is the control of society itself for the common good, as shown by Ward in his masterly memoir on 'Dynamic Sociology,' which it must suffice to mention merely.

Exact knowledge began with the remote and progressed toward the near; with every stage of progress it has been a power for the conquest of natural forces and conditions, has exalted intellectual mankind above all brainless or small-brained creatures, and has made continually for human welfare and happiness; and now, that the methods and purposes of science are extending to the human body and brain, it cannot be doubted that these, like all other material things, will be controlled and reconstructed for the good and the glory of intelligent Man. This is the end of the Science of Humanity.

W J McGEE.

THE AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

SECTION F.—ZOOLOGY.

The officers of the Section were as follows:

L. O. Howard, Washington, Vice-President; C. C. Nutting, Iowa City, Ia., Secretary; F. M. Webster, Councillor.

Sectional Committee: L. O. Howard, Vice-President, 1897; C. C. Nutting, Secretary, 1897; Theodore Gill, Vice-President, 1896; D. S. Kellicott, Secretary, 1896; Charles Sedgwick Minot, Henry F. Osborn, Wm. H. Ashmead.

Member of Nominating Committee: Wm. H. Ashmead.

Committee to Nominate Officers of Section: The Vice-President and Secretary and Charles Sedgwick Minot, Theodore Gill, F. M. Webster.

The scientific papers presented were as follows:

The Spread of Land Species by the Agency of Man with special Reference to Insects. Address of Vice-President Dr. L. O. Howard. Printed in Science, Sept. 10th.

(1) *On the Relationships of the Nematognaths.* By Theodore Gill, M.D., LL.D., Professor of Zoology, Columbian University, Washington, D. C.

The Nematognaths have been considered by most ichthyologists to be most nearly related to the Ganoids or even associated with them in the same order. Their entire structure, however, indicates that they are most nearly related to the Plectospondyls, and they may even associate in the same superorder for which the name Ostariophysi of Sagenmehl may be adopted.

(1) *On a Collection of Cephalopoda from the Albatross Expedition.* By Wm. E. Hoyle, Owens College, Manchester, England.

(6) *On the Sarcostyles of the Plumularidæ.* By Professor C. C. Nutting, A.M., Iowa City, Iowa.

The morphology of the Sarcostyles has been investigated by various writers from the middle of the century to the present. They are composed of ectoderm, endoderm and, according to most writers, a solid axial rod.

A body cavity was described by one of the earliest writers and redescribed by the present writer. The Sarcostyles are undoubtedly degraded 'persons' of the hydroid colony.

The function of these structures is not well understood. It appears to be partly defensive, partly prehensile and partly offensive. The function of scavengers and digestive organs has also been ascribed to them.

(8) *Notes on the Development of Drasteria erechtea.* By Professor F. M. Webster, Wooster, Ohio.

The paper gives the results obtained from rearing larvæ from the eggs to adults, and shows the individual variation of each, both in habit and appearance, the latter being the object of the studies.

(9) *Brood XVI. of Cicada septendecim in Ohio.* By Professor F. M. Webster, Wooster, Ohio.

The paper deals with the occurrence of Brood XVI. of *Cicada septendecim* in Ohio, in 1897. The area over which it has been observed is indicated; the influence of natural enemies is discussed and the probabilities of its becoming extinguished are explained.

(10) *Notes on the Embryology of the Pig.* By Dr. Charles Sedgwick Minot, Readville, Mass.

(1) *The Hypophysis.* There is a true infundibular gland, which is homologous with the saccus vasculosus of Teleosts, and is identical in form and connections with the embryonic saccus. The duct of the gland becomes a solid stalk.

There is also a true hypophysis, which develops a vestibule and gland-tubes homologous with the same parts throughout the vertebrate series.

(2) *The Cardinal Vein.* It is a striking peculiarity of transverse sections of pig-embryos that in the region of the Wolffian body no distinct vein appears, corresponding to the cardinal vein, usually found on the dorsal side of the Wolffian body. This is due to the fact that in the pig the cardinal vein, after entering the cephalic end of Wolffian body, breaks into a multiplied sinus, in which are lodged the Wolffian tubules. Another peculiarity of the cardinal vein is that it does join the jugular to

form the transverse Ductus buvieri, but joins instead the great hepatic vein (Ductus arantii) not far from the heart.

(3) *Allantoic Villi.* The stalk of the Allantois begins to form on its cephalad side within the abdomen a series of lobulated outgrowths, which gradually increase until they occupy a relatively considerable space in the abdomen. These villi consist of a cuboidal mesothelium covering a mass of matricial or ground substance, in which are scattered a few cells of mesenchymal character. The villi are beginning their development in embryos of 14.0–17.0 mm., and are already reduced in embryo of 24.0 mm. The author has no surmise to offer as to their function. Nothing similar to them is known in other mammals.

(11) *Harvard Embryological Collection.* By DR. CHARLES SEDGWICK MINOT, Readville, Mass.

The collection consists mainly of series of sections of vertebrate embryos. It is expected ultimately to have representatives of several divisions of the Mammalia, and of the principle types of non-Mammalian vertebrates.

The work of forming the collection is going forward with the following forms :

Man	Necturus
Dog	Amia
Pig	Amiurus
Rabbit	Batrachus
Chick	Acanthias
Lacerta	Torpedo
Frog	Petromyzon
Amblystoma	Amphyoxus

The plan is to select for each form a carefully graduated series of stages, and to make of each stage three complete series of sections in three planes, the transverse, the sagittal and the frontal, or if the embryo is curved or twisted the three planes are chosen at right angles to one another. A drawing of each stage is made. A double catalogue is kept; the first, in book form, is the entry-catalogue, and records all details of preservation, cutting, staining and mounting. The series of sections are numbered according to their order of entry. The second catalogue is on cards, which are arranged first according to species, second under each species according to stage. Every series of sections has a separate entry number and a separate card. Every section is counted and the sections of every series numbered. At the present time there are about one hundred series completed.

The collection is intended primarily for investigators, and is open to all competent investigators working in the Embryological Laboratory. It is hoped that it will increase during years to come, in size and still more in usefulness. So far as known to the writer, it is the first collection of the kind to be started.

(12) *Organic Selection.* By PROFESSOR H. F. OSBORN, Columbia University, and PROFESSOR E. B. POULTON, Oxford University. Duplicate title (see No. 25).

(14) *Characters for Distinguishing the North American Species of Ceresa.* By WM. H. ASHMEAD, United States National Museum, Washington, D. C.

An explanation of the application of recently discovered morphological characters to the classification of the Homopterous genus *Ceresa.* The author points out the fact that many of the genera in the Membracidæ are merely dimorphic forms of other genera.

(23) *Reconstruction of Phenacodus primævus, the most Primitive Ungulate.* By PROFESSOR HENRY F. OSBORN, Columbia University, New York.

This paper is accompanied by the remounted skeleton of Phenacodus and a wax model executed by Charles Knight. As originally mounted in Professor Cope's laboratory, the famous skeleton of *Phenacodus pri-*

mævus conveyed a very imperfect impression of its actual form and proportions. Several serious errors were committed by the restorer, the most important of which was the implanting of two of the cervical vertebræ in the tail. The author, therefore, considered it advisable to completely remount the animal, and this has been done by Mr. Adam Herman and Mr. Martin, of the American Museum, at an expenditure of five months' time.

The animal is placed as nearly as possible in a natural position. It shows that the feet were not plantigrade, or soled upon the ground, but digitigrade, as in the Tapir. The body is characterized by the great convexity of the back, characteristic of the carnivore and of all early ungulates. A further carnivorous feature is the great development of the hind quarters and of the tail. The disproportion between the hind and the forequarters is heightened by the extremely small size of the head, containing a brain which was about the size of that of the opossum, which has been fully described by Cope.

(24) *Homologies and Nomenclature of the Elements of the Molar Teeth.* By PROFESSOR HENRY F. OSBORN, Columbia University, New York.

After a brief review of the tritubercular theory of Cope, the writer spoke of his hypothesis advanced at the American Association meeting in 1891, that the multitubercular teeth of the Multituberculata and Monotremata were also of tritubercular origin. This hypothesis seems now to be confirmed by the teeth of Gomphodontia, especially of the genus *Diadermodon*, by Professor Seeley in the Narvo Beds of South Africa, of Permian age.

The various Gomphodonts in these beds present molar teeth of more or less regular tritubercular pattern. Related to them in skull structure is Tritylodon—a typical multituberculate. This indicates that from the trituberculate Gomphodonts Tritylodon and other multituberculates may have taken their origin. The paper was discussed by Professor Minot and Dr. Gill.

(25) *Modification and Variation and the Limits of Organic Selection.* By PROFESSOR HENRY F. OSBORN, Columbia University, New York, and PROFESSOR EDWARD B. POULTON, Oxford University, England.

[An account of these papers will be published in a subsequent issue of SCIENCE.]

(26) *Geographical Distribution of the Golden Warblers.* By HARRY G. OBERHOLSER, Biological Survey, United States Department of Agriculture, Washington, D. C.

The so-called Golden Warblers form a group of some twenty-five species and subspecies in the genus Dendroica, and are distributed over almost all the Nearctic region, together with the Antillian, Colombian and Central American subregions of the Neotropical. The greatest differentiation of forms occurs in the West Indies, where the distribution of many of the species is somewhat anomalous.

(27) *Modern and Older Theories of Mimicry Illustrated by Butterflies of the Genus Hypolininas.* By PROFESSOR EDWARD B. POULTON, Oxford University, England. [To be published in SCIENCE in abstract.]

WM. H. ASHMEAD,
Press Secretary.

FIELD WORK OF THE UNITED STATES COAST AND GEODETIC SURVEY.

MOST of the reports from the field parties of the United States Coast and Geodetic Survey are now in, and it is possible to summarize the work for the fiscal year ending June 30, 1897.

The operations have been, as usual, widely distributed, and cover localities on the Atlantic, Gulf and Pacific coasts, including Alaska. Much work has also been

done in the interior. Thirty land and ten parties operating on the sea were on duty during the year. The results of the labors of the land parties were as follows:

The new topographical survey of the shores of Buzzard's Bay, Massachusetts, finished.

San Francisco Harbor and Bay, nearly finished.

The Los Angeles base line in California, connected with the existing triangulation and a scheme developed by means of which a grand scheme of trigonometrical figures may be carried northward. This base, although measured years ago, had never been adequately transferred to the triangulation.

The chronometric determination of the longitude of Unalaska and Kadiak Islands, on the Aleutian Peninsula, Alaska.

The determination of the magnetic elements (declination, dip, and horizontal intensity) in nine Western States, principally in California, Montana, North and South Dakota and Nebraska.

Precise levelling in Kansas and Mississippi.

Trigonometrical work in Maryland and Delaware, completing the last direct triangulation on the Transcontinental Arc from Cape May to San Francisco.

Measure of a base at Salt Lake City with the new Duplex base apparatus.

Topography on Long Island.

Base measures in Kansas.

Triangulation at the mouth of Chesapeake Bay.

Topography and triangulation at the mouth of the Patapsco River, and on the Chester River, Maryland.

Reconnoissance in Nebraska.

Telegraphic longitude in Massachusetts, New York, Washington and Canada.

Hydrography, topography and triangulation of Lake Pontchartrain, Louisiana.

Traverse line across the Peninsula of Florida from Fernandina to Cedar Keys to connect the Gulf and Atlantic Coast triangulation.

Continuation and completion of the oblique arc along the Appalachian Chain from Maine to Mobile.

New survey of the Pribilof Islands, Bering Sea.

Connection of longitude station at Montreal with primary triangulation in New England.

Other unimportant operations were also carried on, the above being a general summary of the greater divisions of the work.

The work of the parties operating from vessels was:

Hydrographic work on the New England coast and on the Chesapeake Bay.

Special surveys on the outer bar at Brunswick, Georgia, and Long Island Sound.

Examination of Savannah River Entrance and the mouth of Elizabeth River.

Survey of Lake Pontchartrain, Louisiana, and Brazos River, Texas.

General Hydrographic work in Alaska and in San Francisco Bay.

Special work has also been done in laying out speed trial courses for testing the battleships and torpedo boats of the navy; soundings for new positions of light vessels, current observations, etc., etc.

As will be seen, the greatest activity in the land parties has been displayed in the fields of Topography, Triangulation and Magnetism. The original scheme of primary telegraphic longitudes has now been completed and the definitive values of the standard longitudes of the United States have been deduced.

The principal work of the sea parties has been on the coast of New England, in Alaska and in San Francisco Bay.

The operations during the fiscal year just closed have been productive of important results from both commercial and strategic standpoints. The completion of the survey of Buzzard's Bay, the beginning of the work near Baltimore and the rapid progress made at San Francisco are all in the interest of national defense, while the accurate determination of the longitude of Unalaska and Kadiak Islands furnishes a check to the reckoning of all vessels bound from Sitka to the mouth of the Yukon. The new speed trial courses are valuable auxiliaries to the navy, and examinations for new positions of light vessels are necessary alike to the naval and merchant marine.

The aid given to the Seal Fishery Commissioners in the way of transportation, etc., to the Guadaloupe Islands, and the cooperation with the engineer department of the army on the Brazos River, Texas, must be reckoned as not the least important incidents of the work from a commercial and

practical point of view. The progress made in all branches of the work, although comparing favorably with the operations of previous years, has not been as apparent as usual on account of many pieces of patch work made necessary by the rapid strides in the past. The work across the peninsula of Florida from Fernandina to Cedar Keys was broken off at the beginning of the Civil War and remained untouched until last winter. It will be completed during the coming season. The Transcontinental Arc begun in 1871 has just been completed by the direct chain of triangulation from Washington to Cape May, thus cutting off the older and less reliable work by way of Delaware Bay. This work, of the highest importance in international geodesy, together with the completion of the oblique arc from Maine to Mobile, already mentioned, marks an era in American geodesy and contributes new and valuable information as to the size and shape of the earth.

P.

CURRENT NOTES ON PHYSIOGRAPHY.

THREE DRIFT SHEETS OF IOWA.

The work of Calvin on Iowan drift is continued by Bain (Iowa Geol. Survey, VI., 1896, 429–476), whose report is of much geographical interest. The Kansan drift forms the surface of rather more than the southern half of the State; it is deeply weathered, the granite boulders being badly rotted and the limestone leached out; the surface is well carved by streams and holds no lakes. The Iowan drift occupies somewhat less than the northern half of the State; it is also well dissected, but less completely than the Kansan, and sloughs remain here and there on its surface. No moraine is found along its margin; but extensive loess deposits are spread forward from it over the dissected surface of the Kansan sheet. The Wisconsin drift is well developed in a strong lobe that invades the State to a little south of its center, and thus overlaps both the older sheets. Its surface is much less dissected by valleys, and many lakes remain upon it. Its border is marked by a strong moraine, from which extensive gravel trains are prolonged down the outer valleys. The diversity of the glacial period and the considerable value of inter-glacial epochs thus find much support from the Iowan geologists.

A special discussion of erosion curves accompanies the account of the Kansan drift topography; and it is pointed out that many of the rivers of to-day, although occupying valleys carved in the drift, nevertheless follow preglacial or interglacial courses, and are therefore to be called resurrected, following McGee's use of this term.

MOUNT ST. HELENS.

Lieut. C. P. Elliott, U. S. A., gives an interesting account of Mount St. Helens (Nat. Geogr. Mag., VIII., 1897, 226–230), from which many items appropriate to its class may be gathered. The mountain stands west of the Cascade range divide, its truncated cone reaching a height of 8,608 feet. Its scopes have been dissected by ravine streams and repaired by lava streams, the latter often interfering with the escape of the former and producing lakes and swamps. The ravines have the radial course usual on dissected volcanoes. The flows of lava and volcanic sand descend from near the mountain summit, running around hills as a river passes islands, and 'filling up the country' in their course. Spirit lake, five miles northeast of the summit, occupies a valley dammed by sand, ashes and pumice, which are there very plentiful. A flow that descends five miles to the southwest of the summit first nearly fills in the depression toward Green buttes; then passing around the buttes, the lava unites and fills in between Goat mountain and a ridge northeast

of it, forming a large swamp; further on it obstructs a valley on the south, forming Lake Merrill, and finally Kalama river falls over the end of the flow. Many large springs emerge from beneath the lava flows.

MAARE OF THE EIFEL.

Halbfass presents the results of soundings and temperature observations in the eight Eifel maare (Petermann's Mitt., XLIII., 1897, 149–153; with more detail in Verh. Naturh. Vereins, Bonn, 1897). A ninth maar (Wanzenboden) is only two or three m. deep, and in part thickly occupied with reeds; the Hinkelsmaar and many other basins are now converted into dry meadows. Those which still hold water deepen from margin to center; at first gradually, then more rapidly with slopes of 20–30°, and again gently near the center. Only the Laacher See is large enough to have a well defined flat central floor. The Pulver maar is the deepest (74 m.) of all German lakes outside of the Alps. The shore lines approach a circular outline, but the Meerfelder maar is like a half moon, occupying only half of its circular basin. Much statistical statement of fact with arithmetical comparison of the different maare is given. The life-history of the lakes is not directly considered.

THE EASTERN ARCTIC SEA.

Supan gives a review of Nansen's polar expedition, from which the following notes on the eastern Arctic sea (the northern part of the 'eastern hemisphere') are taken (Petermann's Mitt., VII., 1897, 158–163). Sheets of ice occupy much of the surface, continually drifted by currents and winds; now torn apart and opening water channels, now pressed together and forming walls and ridges. The latter reach heights of nine m., and offer the greatest obstacles to sled travelling. The remnants of former ridges drift about in berg-like masses with steep walls. The drift ice here is contrasted with the much thicker pack ice west of Greenland. The winter snow began melting in June, and the firm drift ice was not revealed till the end of summer. Its color is then a dirty brown, caused chiefly by mineral dust. Fresh water pools are formed on the ice surface, surprisingly rich in microscopic organisms. The ice increased in thickness slowly through the winter to June, varied until August, and decreased to early winter. Thickening in summer is ascribed to freezing underneath of fresh water supplied by melting snow above. In early spring the ice was coldest, from —16° to —30°C. In summer it approached the melting point, and then became plastic, so that crushing took place without sound; bending frequently replaced breaking.

The discovery of the great depth of the Arctic, 3000–3900 met., where traversed by the Fram, is regarded as the most important geographical result of the expedition. Polar lands are, therefore, not to be expected. A sample of serial temperature soundings gives a surface layer 200 m. deep at —1°C.; a second layer, 660 m. thick, with mean temperature of +0°.22 C., and about 3000 m. of deep water with mean temperature of —0°.57 C. The surface layer has least salt, and the intermediate layer most. The latter is supplied from the North Atlantic, dipping beneath the Arctic surface layer because its density is determined by salinity rather than by temperature.

W. M. Davis.

Harvard University.

CURRENT NOTES ON ANTHROPOLOGY.

ARREST OF DEVELOPMENT IN HUMAN GROUPS.

On this subject Professor Schrader has a curious article in the *Revue Mensuelle* of the Paris School of Anthropology. His conclusion is that the failure to advance or the actual retrogression of peoples and societies is a question of lack of adaptation to environment. This is not new; indeed, it is

quite old. His novel proposition is that, given a better environment, the most inferior race may become superior to all others. "That which we are to-day, others may be to-morrow." He also claims that a race long resident in a given *Milieu* becomes best suited to it, and, granted equal facilities, is sure to surpass all other races there. He quotes the native population of Mexico in illustration. Conquered by Cortes, beaten into the dust by brutal European rule, it has seized the arms of its conquerors, and now is rising in its might above its ancient invaders. "Is it an illusion," he asks, "that reveals to us in the physiognomy of the Yankee the hard, bony face of the Red Skin?"

PRINCIPLES OF THE STUDY OF MYTHOLOGY.

In a recent number of the monthly journal *Nord und Sud*, Dr. Thomas Achelis has a suggestive article on the relations of mythology to ethnography. He advocates and illustrates the principle now constantly gaining ground among advanced anthropologists, that if we learn accurately the daily life of primitive peoples, understand the impressions they receive from their environment and the mental impulses they gain from language and the interchange of ideas, then psychology is prepared to explain their religious perceptions according to definite and fixed principles. Similarities or identities between remote tribes will no more call for the theory of unity of source than the mere similarity of the sound of words would justify the etymologist in adopting the same theory for its explanation.

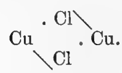
In all of his writings Dr. Achelis has pursued this same line of thought, and, although this has not recommended him to those of his reviewers who adhere to a more antiquated philosophy, there can be no question but his is the 'party of the future.'

D. G. Brinton.

University of Pennsylvania.

NOTES ON INORGANIC CHEMISTRY.

The seventh article of the series by Alfred Werner in the *Zeitschrift für anorganische Chemie*, on the constitution of inorganic compounds, describes molecular weight determinations of a large number of salts in organic solvents, such as piperidin, pyridin, methyl sulfid, etc. In the case of many salts regarding which there has been considerable doubt, the results were in accord with the monomolecular formula, as $AlCl_3$, $FeCl_3$, $FeCl_2$; also $CoCl_2$, $CoBr_2$. Tin (stannous) and lead salts were also found to be monomolecular. Cuprous salts were in general normal ($CuCl$, CuI, etc.), but showed considerable tendency to polymerize by doubling. Cuprous cyanid appeared only in dimolecular form, $Cu_2(CN)_2$. The silver halogen salts showed a strong tendency to polymerization, the iodid having a molecular weight corresponding to $(AgI)_2$, while the chlorid (and bromid) were between $(AgCl)_2$ and $(AgCl)_3$. Silver nitrate, however, had the normal formula $AgNO_3$. Professor Werner is of the opinion that in the polymerized molecule the metal atoms are not united together, but that the union is between metal and non-metal, as



It would seem possible, however, that the union might subsist through the medium of the non-metallic atoms, which would account for the greater tendency to polymerization on the part of the cyanids.

Boric acid has a quite extended use as a food preservative, but the data as to its effect on health are very meagre. R. A. Cripps, in the *Analyst* for July, recounts a series of experiments on the action of boric acid on the digestive ferments. His results are the following: With malt-extract in presence of 0.01% to 1% boric acid, starch was dissolved completely in 12 minutes, not

completely in 10 minutes. With saliva, starch was dissolved in the presence of 1% or less boric acid in from 8.5 to 11.5 minutes; with no boric acid 11.5 minutes was required. With pepsin, the digestion of egg albumen was not retarded in the presence of 1% boric acid. With zymin, milk albumen with 1% boric acid was completely peptonized in $2\frac{1}{2}$ hours. With Blumenthal's chymosin, a far larger amount of boric acid than was necessary for preservation of food did not affect the fermenting action unfavorably. While boric acid thus does not retard digestion, its physiological action still remains to be finally settled.

J. L. H.

SCIENTIFIC NOTES AND NEWS.

THE 'ENCHANTED MESA' OF NEW MEXICO.

A SURVEY has just been made of the 'Enchanted Mesa,' or Mesa Encantada, of New Mexico, by a party sent out by the Bureau of American Ethnology.

This mesa was brought into prominence several years ago through the work of Bandelier, who ascertained that the neighboring Acoma Indians have a tradition that their ancestors formerly occupied the summit, but abandoned it, together with a part of the tribe, in consequence of the destruction of the pathway leading up one of its precipitous sides; the catastrophe, which was doubtless due to a cloudburst, being ascribed to supernatural agency. The same tradition was subsequently obtained by C. F. Lummis, a well-known student of the Southwestern Indians, and also (with some confirmatory evidence) by F. W. Hodge, of the ethnologic bureau. The traditional catastrophe was so magnified by repetition and so enveloped in mystery that the Indians, and after them the white settlers, had come to regard the mesa as inaccessible.

Two years ago Mr. Hodge, then studying the Acoma Indians, planned to visit the summit in order to seek for traces of the alleged occupancy in prehistoric times; but he was deterred by regard for the sentiments of the Indians, who held the eminence sacred. During the present season, Professor William Libbey, of Princeton University, after elaborate preparations, ascended the mesa, without finding (so far as the accounts published in the newspapers indicate) evidence of occupancy. Reports of this failure duly reached the neighboring Indians; they were annoyed by the suggested impeachment of their tradition, and were thereby the more easily induced to permit the ethnologic party to visit their holy place. So, on September 3d, Mr. Hodge, accompanied by Major George H. Pradt, of Laguna, New Mexico, a U. S. Deputy Surveyor; Mr. A. C. Vroman, a photogropher of Pasadena, California; Mr. H. C. Hayt, of Chicago, and two Laguna Indians, proceeded from the Indian pueblo of Acoma to the foot of the mesa, three miles distant, where they were joined by three Acoma Indians. After measuring the eminence by triangulation (the mean of two determinations is 431 feet above the plain on the west), the party at once ascended along the ancient route, and encamped on the summit for the night. During the afternoon and the next day Mr. Hodge examined the ground critically, while Major Pradt made a survey of the mesa, and Mr. Vroman secured a number of photographs. Several potsherds, two stone axes (broken), a fragment of a shell bracelet and a stone arrowpoint were the chief evidences of former occupancy found on the narrow storm-swept crest; but abundant potsherds, etc., were found in the talus swept down from the summit. All vestiges of the ancient trail ascending the talus, and continued thence to the summit by hand and foot holes in the solid rock, have been obliterated; but some traces of the holes remain. This verification of an Indian tradition notable for inherent evidence of accuracy is peculiarly gratifying to students of anthropology.

Except for the easily-removed opposition of the Acoma Indians, no difficulty was found in ascending the mesa, save for a space of a few feet at the top of the cleft; this was easily crossed on a light extension ladder carried to meet emergencies, and might have been passed with the aid of a geologic hammer to cut a few hand-holes in the steepest part of the rock.

W J M

GENERAL.

WE record with much regret the death of Mr. Theodore Lyman, the only honorary member of the National Academy of Sciences, formerly member of Congress and a distinguished officer in the army during the Civil War. Colonel Lyman was born in 1833 and died on the night of September 9th, at his summer home, at Nahant, Mass. He studied under Louis Agassiz, whose daughter he married. Colonel Lyman was a zoologist and geologist of distinction. He was the representative of a class more common in Great Britain than in the United States—a man of wealth, public spirit and wide culture, who contributed both directly and indirectly to the advancement of education, science and civilization.

THE membership of the National Academy of Science is now eighty-three. The deaths and elections to the Academy during the last six years have been as follows:

Deaths.		*Elections.*
	1891.	
Julius E. Hilgard, John Le Conte, Joseph Leidy, Miers F. Longstreth.		None.
	1892.	
T. Sterry Hunt, Joseph Lovering, J. S. Newberry, Lewis M. Rutherfurd, William P. Trowbridge, Sereno Watson.		Carl Barus, S. F. Emmons, M. Carey Lea.
	1893.	
W. H. C. Bartlett, F. A. Genth.		None.
	1894.	
Charles E. Brown-Sequard, Josiah P. Cooke.		None.
	1895.	
James D. Dana, John Newton, James E. Oliver.		W. L. Elkin, C. S. Sargent, W. H. Welch, C. O. Whitman.
	1896.	
Thomas L. Casey, G. Brown Goode, Benjamin A. Gould, H. A. Newton.		C. D. Walcott, R. S. Woodward.
	1897.	
E. D. Cope, M. Carey Lea, A. M. Mayer, J. H. Trumbull, F. A. Walker, Theodore Lyman.		E. W. Morley, C. S. Minot, W. H. Dall, F. A. Gooch.

The original act incorporating the National Academy, in 1863, limited the number of ordinary members to fifty, but this restriction was removed in 1870. A wise conservatism has regarded one hundred members as a suitable limit, but there appears to be no reason why the membership should decrease while the scientific activity of the country increases. Fifteen new members of the Royal Society are elected annually.

THE seventh annual directory of the Scientific Alliance of New York, for the year ending 1897, has been published by the Council. The number of members is 1,055, an increase of forty over last year. The membership of the several societies comprising the Alliance is as follows:

The New York Academy of Sciences, resident members and fellows,	284
Torrey Botanical Club, active members,	221
New York Microscopical Society, active members,	88
The Linnæan Society of New York, resident members,	169
The New York Mineralogical Club, total membership,	65
American Mathematical Society, local membership,	47
The New York Section of the American Chemical Society, active members,	282
The New York Entomological Society, active members,	48

ABOUT fifty members of the British Association from Great Britain, including Lord Kelvin, Lord Lister and Sir John Evans, have taken part in the extended excursion to the Pacific Coast following the Toronto meeting of the Association.

THE item, circulated by the newspapers, to the effect that four Ohio men of science had been treated with scant courtesy at the meeting of the British Association, is entirely without foundation. The complaint comes from only one of the number, a collector of fossils and a manufacturer of casts of the same, who failed to secure an announcement, concerning his specimens, in the geological section. There was, of course, no international feeling involved in the matter, The other three, professors in Cleveland and Oberlin, whose names were used

without their knowledge, repudiate any responsibility for the complaint, and say that they experienced nothing but perfect courtesy while at the Toronto meeting. Indeed, the original report contains numerous errors, for which the original complainant himself does not wish to be held responsible.

FRANZ PULSZKY, formerly director of the National Hungarian Museum and superintendent of the public museums and libraries of Hungary and a writer on archæological subjects, has died, aged 82 years. He took an important part in the attempts to establish Hungarian independence, and visited America with Kossuth, being long under sentence of death for treason against Austria.

THE Hon. Charles D. Walcott, Director of the U. S. Geological Survey, left San Francisco on September 7th, for the Yosemite Valley, accompanied by Assistant F. B. Weeks. According to a dispatch to the New York *Evening Post* he proposes to make topographical maps, on a two-mile scale, of all the forest reserves in California, which, including recent additions, comprise no less than 6,647,000 acres. On these maps the distribution of forests will be pointed out, showing the commercial and the non-commercial timber, the agricultural lands included in the forest reserves, and all settlements, roads, houses and other improvements upon the national forest domain. Since leaving Washington on July 23d Mr. Walcott has inspected the forest reserves in Wyoming, Montana, Idaho, Washington and Oregon.

THE Jackson-Harmsworth expedition duly reached London on September 3d. The results of three winters spent in scientific work in Franz Josef Land will doubtless include valuable contributions not only to Arctic geography and meteorology, but also to geology, zoology and botany.

MR. WALTER WELLMAN, the journalist and Arctic explorer, has returned to New York after a visit to Norway for the purpose of making arrangements for his proposed Arctic expedition. According to statements in the daily papers, he proposes to sail from Bergen in a staunch steamship on June 13th of next year for Franz Josef Land. He expects to establish a supply station at Cape Flora and to reach Cape Fligely before the winter sets in. Then, in 1899, he intends to try to traverse on sleds the 550 miles to the Pole.

MR. A. W. GRABAU, of Boston, is continuing the field excursions for the study of natural history begun last year and made possible by the generosity of an anonymous donor. He met applicants for membership at the Museum of Natural History on September 11th and gave an account of the course in marine zoology which will take the class to the seashore near Boston. At two o'clock the party left for Beverly. Other excursions have been arranged as follows: September 15th, Revere Beach; September 18th, Nahant; September 22d, Marblehead; September 25th, Swampscott; September 29th, Bass Point.

THE New York *Evening Post* reports that the Chabot Observatory, of Oakland, Cal., has decided to send a special expedition to India to observe the total eclipse of the sun. It will be headed by astronomer Burckhalter, whose expenses will be paid by William Pearson, of San Francisco. Dr. George C. Pardee will provide a new lens for the use of the observers. The expedition is, of course, entirely distinct from that to be sent out by the Lick Observatory, the funds for which were provided by the late Mr. Crocker.

THE Prince of Monaco, in his steam yacht, the Princess Alice, is said to have completed a season's researches in the Azores.

IN view of the outbreak of yellow fever at Ocean Springs, the Surgeon-General has instructed Dr. Wasdin to investigate the disease in accordance with Dr. Sanarelli's methods and has forwarded him the necessary outfit.

THE daily papers report Dr. H. B. Guppy, an English naturalist, returned to Napoopee, Hawaii, on September 1st, after spending twenty-three days alone on the summit of Mauna Loa, at an elevation of 13,000 feet above sea level. He carefully explored the crater of the volcano and made collections of the fauna and flora.

AN Engineers' Club has been established in Chicago, the object of which is to be the advancement of engineering in its several branches, the professional improvement of its members,

and the encouragement of social intercourse among men of practical science. It is proposed to publish proceedings, to maintain a library and a collection of drawings and models.

A NATURAL Science Association was organized in Jersey on August 5th, with Dr. A. C. Goodfrey as the first President.

THE French Society of Civil Engineers appointed some time since a committee to consider the propositions that have been made for the decimalization of time and angles. This committee has made its report adverse to the proposed reform but recommending the numbering of the hours of a day continuously up to twenty-four.

IN connection with the Brussels Exposition there was held an International Congress of Commerce and Industries from September 7th to 11th.

THE library at Massillon, Ohio, has recently received generous gifts. The residence of the late Mr. Nahum Russell, valued at $30,000, has been presented to the city by his daughters, and Mr. J. W. McClymonds has given an endowment fund of $20,000.

THE British 'blue-book,' recently issued relating to the nature and extent of the trade of Australia and adjacent colonies, contains some interesting and useful information for American manufacturers. It appears that, in New Zealand, for example, Germany and Belgium, not Great Britain, send in the greater part of the supply of firearms. Glassware comes from Belgium; saws, almost exclusively, from the United States. Axes come exclusively from the United States, and carpenters' hammers from the same source mainly, though England still furnishes the heavier and ruder sorts, such as are used by blacksmiths and machinists. Germany and Belgium supply nails, and the former is gradually encroaching upon the market for machine tools, formerly controlled by England. All the agricultural machinery is furnished by the manufacturers of the United States, who produce the most remarkable combination of lightness and strength, and yet sell at lower prices than even Continental nations can yet attain. The reasons for Great Britain's 'temporary decline' are said to be: Conservatism, lack of versatilty and adaptability, disdain of methods successfully adopted by competing vendors, stringency in calling for payment and 'a general haughtiness in trading transactions.' As one of the London trade papers says: "When a wealthy London corporation builds and equips a London railroad with American plant it is time for English manufacturers to see themselves as others see them."

IT is stated in *Machinery* that Acetylene is now in use in several of the Paris omnibuses. The generator weighs about 29 lb., and is carried under the front steps. Each load of carbide is about 0.71 lb., and produces about 3 cubic feet of gas, which is enough for 6½ hours, with a light of 16 candles. The pressure is regulated so as not to exceed 4 inches of water. The cost is less than that of petroleum. Electrical accumulators to do the same work weighed nearly 3 cwt., and did mischief, so that they were glad to give them up.

THE *Philosophical Review*, edited by President Schurman and Professors J. E. Creighton and James Seth, of Cornell University, and published since its foundation by Ginn & Co., will next year be published by The Macmillan Company.

THE Principles of Sociology, by Professor Franklin H. Giddings, of Columbia University, of which a third edition has recently been published by The Macmillan Company, has been translated into French and German, and a Spanish translation is announced for early publication.

VOLUME two of the *Maryland Geological Survey Reports*, which will contain a description of the building and decorative stones of the State, is well advanced and will be issued the coming winter.

PRESIDENT C. G. WILSON, of the New York Board of Health, has made a report showing the remarkable decrease in the death-rate of New York City since 1823. Figures for the first eight months for each of the last six years.

	Estimated Population.	Deaths, Jan. to Aug., inclusive.	Death rate.
1893.......	1,758,010	31,982	27.3
1894........	1,809,353	29,397	24.4
1895........	1,879,195	30,699	24.5
1896........	1,934,077	30,307	23.5
1897........	1,990,562	26,866	20.2

THE report of the committee of the British Council on Education on schools for the blind and deaf, for the past year, has been published as a Blue-book, signed by the Duke of Devonshire and Sir John Gorst, and is abstracted in the London *Times*. During the year ending August 31, 1896, the number of certified schools increased from 84 to 91. These schools provide accommodation for 1,476 blind children (268 day scholars and 1,208 boarders), and for 3,004 deaf children (1,699 day scholars and 1,305 boarders). The total grants paid for the year amounted to £15,629 12s. A general report by the Rev. T. W. Sharpe, Senior Chief Inspector, follows, covering the year ended March 31, 1897. He states that the year has been marked by steady progress, and pleads for higher payment of teachers, both for the blind and deaf. The hope is expressed that a recent return called for by the department will produce some result. This return requires each school authority to give the name of every blind and deaf child in its district between the ages of 5 and 16 and 7 and 16 respectively. The address of the parent or guardian and the provision made under the statute for the education of the child are also required. With regard to deaf children, Mr Sharpe states that the teaching on the oral system in some institutions is very imperfectly carried out, and that oral teaching is in danger of being discredited from the fact that, however excellent the school teaching may be, the continued practice of speech outside the schoolroom is either left to chance or so mixed with signs that it receives very little care.

UNIVERSITY AND EDUCATIONAL NEWS.

DR. ANDREWS has withdrawn his resignation from the presidency of Brown University.

WE should be glad to welcome a 'Cosmopolitan' reading circle or Correspondence School, even though its standard should be no higher than that of *The Cosmopolitan* magazine. But the projectors of the 'Cosmopolitan University' cannot make silver equal to gold by debasing a name. Fortunately, the performance is illegal in the State of New York. Section 33, Chapter 378, of the laws of the State reads as follows:

> No individual, association or corporation not holding university or college degree-conferring powers by special charter from the Legislature of the State or from the regents shall confer any degrees, or after January 1, 1893, shall transact business under or in any way assume the name university or college, till it shall have received from the regents under their seal written permission to use such name.

The minimum requirements for a degree-conferring institution have been carefully defined by the regents, and it is scarcely needful to state that these cannot be met by an annex to a magazine.

AN editorial in the last number of the *Educational Review* on the Brown University incident concludes with the moral: "What a comment this occurrence is on the project for a national university at Washington, that is still kept alive by earnest but, we believe, misguided men!" The article was written on the assumption that "Rhode Island and Providence will not support an educational institution in which an officer of prominence holds views antagonistic to their own on an economic question that is under present discussion." The frank and wise declaration of the corporation of Brown University for academic freedom, even under aggravating circumstances, shows that the *Educational Review* is needlessly pessimistic in its point of view. It would, indeed, be better to have a struggle for academic freedom in a national university and lose than not to have the university and the struggle. The effect on other universities and on the education of the people would be beneficial, and the defeat would be but temporary. Neither pedagogy nor politics is at present a science, and they only come within the scope of this JOURNAL in so far as they concern the advancement of science. But an affiliation of the national scientific institutions at Washington, with power to grant degrees for research, would be the basis for a university in which science and investigation would have the place now held at Oxford, *e. g.*, bythe classics and information. It is a scientific experiment that all men of science should advocate.

THE *Educational Review*, however, appears to

be also pessimistic regarding those whom it calls 'natural scientists,' for the editorial quoted above says: "Devotees of natural science are, as a rule, the most intolerant of all university teachers, especially toward differences of opinion within their own sphere." We have published a number of articles on scientific education, but none of these have betrayed a prejudice against the classics equal to that against modern scientific education shown recently by Professor Wilson, of Princeton; Professor Peck, of Columbia, and President Stryker, of Hamilton, nor equal to that against the classics in the recent program of President Andrews, himself formerly a teacher of classics.

WHILE engaged in promulgation we may remark that President Stryker, who had much to say last winter in regard to 'debasing' the A. B. degree by granting it for scientific studies, has allowed Hamilton College to give the degree of Ph. D. *causa honoris*. This, we believe, is illegal in the State of New York.

THE will of Charles T. Wilder, of Wellesley, Mass., gives more than $100,000 to charitable and educational institutions, including $10,000 each to Robert College at Constantinople, the Armenian School for Girls at Constantinople, the Colorado College at Colorado Springs, Whitman College at Walla Walla, Wash., and Charleston College, Northfield, Mass. In a codicil dated July 27, 1897, Mr. Wilder bequeathed $15,000 to the trustees of Amherst College for the purchase of land for an observatory. The residue of the estate, both real and personal, is left to the executors in trust to be distributed among charitable, educational and religious institutions.

THERE is offered this year at Amherst College a prize of $500 for the best prepared freshman in the classical division and a similar prize of $300 in the scientific division.

THREE new associate professors have been appointed at Oberlin College, Charles Edward St. John, Ph.D. (Harvard), in physics and mathematics; Herbert Lyon Jones, M.S. (Denison), A.M. (Harvard), in Botany, and S. F. McLennan, A.B. (Toronto), and Ph.D. (Chicago), in psychology and pedagogy.

AT Williams College, Mr. Edward V. Huntingdon (Harvard) has been appointed instructor in mathematics and Mr. Frank H. Williams, assistant in chemistry.

DISCUSSION AND CORRESPONDENCE.

AMPHIBIA OR BATRACHIA.

As Professor Wilder * has expressed the hope that the discussion on the proper name of the class variously known as Amphibia or Batrachia 'may continue until all doubts are removed,' I venture to add my contribution. Dr. Baur † has treated the history of the nomenclature in his usual thorough manner, but perhaps has not laid sufficient emphasis on one point (although fully recognizing it himself), which has influenced me more than any others and probably will appeal to Professor Wilder more than the others.

The principle of priority of nomenclature should guide us in the selection of names of large groups as well as those of genera and species, provided there is no counteracting element or objection. It is especially important to retain the names of Linnæus as much as possible.

Linnæus introduced into the system six classes—Mammalia, Aves, Amphibia, Pisces, Insecta and Vermes. These have all been generally retained by succeeding naturalists except Amphibia. While many have adopted Amphibia, however, still more, perhaps, have employed Batrachia. But there appears to be no good reason for this use of Batrachia at the expense of Amphibia.

Amphibia should be retained as a *class* name, as it was at first given *as such*, and the fact that the class as originally constituted contained diverse elements should weigh no more against the adoption than the analogous extensions in the case of *Insecta* and *Vermes* or innumerable genera. The name should be restricted to the typical subdivision of the primitive Amphibia.

The name Amphibia, doubtless, expresses the concept of Linnæus derived from his own observations of living animals, and he must have been most impressed with the metamorphosis of some which he mentions first among

* SCIENCE, August 20, 1897, p. 295.

† SCIENCE, July 30, 1897, pp. 170–174.

biological attributes of the class ('aliis metamorphosin subire'). But however this may be, the name was first limited to the forms undergoing metamorphosis by De Blainville, and there is no reason why that restriction should not be respected.

The name Batraciens, or Batrachia, was given as an *ordinal* name. It was not used as a class name till long after Amphibia had been duly restricted to the class still so called.

If the name Batrachia were usable at all it should only be as an ordinal designation, as Huxley has done. But it cannot be legitimately used as such, because many years before the name Salientia had been introduced by Laurenti for the same order, and most of the best herpetologists of the present time (Cope, Boulenger, et al.), have revived or accept the name for the order so designated.

The name Amphibia was first used as a class name by Linnæus for a group which was certainly very heterogeneous, inasmuch as it included not only the typical Amphibians and reptiles, but also the Marsipobranchs and Selachians, as well as certain true fishes (Lophius, Acipenser, etc.). The class was divested of the fish-like forms by the editor of the Systema Naturæ (Gmelin, 1788), and with these limits it was long retained.

The essential point in the case under consideration is that Linnæus first recognized a *class* intermediate between fishes and birds, whose *typical* representatives pass part of their life in water and part on land, and the apt name Amphibia was given to that class. (The name is eminently suggestive and expressive for the class as now limited.) Batrachia was given long afterwards both as an ordinal and class designation. (The name is quite inapt for many of the species.)

THEO. GILL.

SURVIVAL OF THE ART OF ILLUMINATING MANUSCRIPTS AMONG THE GERMANS IN EASTERN PENNSYLVANIA.

AMONG the interesting objects included in the collection of tools, utensils and paraphernalia, representing the life of the American pioneer, recently made for the Historical Society of Bucks County, Pennsylvania, two curious paint boxes, for a time defying explanation, have at last led to an interesting observation. By degrees, after a series of investigations, beginning on August 20th, I learned that these boxes had contained, in their wooden compartments, the paints and colored inks by which the masters of the German schools in upper Bucks County (discontinued about 1850), taught the art of *Fractur*, or illuminative handwriting done in colors for permanent preservation. The liquid colors mixed in whiskey were contained in the little glass bottles still occupying their pigeon holes in one of the boxes. Other bottles contained inks, and one the varnish, consisting of the gum of the cherry tree diluted in water. A long compartment held the brushes and quill pens.

With these implements the masters of *Fractur*, generally Mennonites (who sometimes instructed pupils in the art as an addition to the ordinary tuition of a schoolmaster), illuminated the title pages of numerous Mennonite manuscript song books still extant in the county, produced elaborate title pages for Bibles, name cards, marriage and death registers, and Scriptural texts. A striking example in the possession of Henry K. Gross, of Doylestown, is a transcription of the 18th verse of the 19th chapter of John with decorated letters and floriated capitals in red, green, brown, blue and black, set above a bar of music, and twelve lines of cursive manuscript, upon which are placed two birds in red, green and black. A pious admonition in red and black text edges transversely the left end, while the lower margin is filled with an alphabet in various text. The borders are floriated and plain red or blue.

Further examples are: A, Title page to Church song book (*Lieder Buch*, printed in Germantown, by Michael Villmeyer, in 1811), name Susanna Fretz upon heart, from which springs a tree with conventional tulips; deep beaded borderings, 1814, colors red, brown, yellow and black, red predominant. B, Title page to manuscript song book, name Susanna Fretz (spelled Fretzin for feminine) in red circle with date 1810; stalks with black leaves and conventional tulips to right and left; foliated border with red leaves on black and yellow ground. C, Title page to manuscript hymnbook; name,

Joseph Gross, illuminated letters, foliated capitals; date, April 20, 1830; double tulips in foliate on yellow ground. D, Title page to manuscript hymn book, name Sarah Wismer; foliated capitals, conventional flowers on heavy stalks; date 1827; colors red, yellow, brown and blue. E, Title page to ditto; name, Elizabeth Nesch (Neschin), with words Dieses Sing-Noten Buchlein Gehoret Mir; Sing Schuler In Der Bedminster Schule; Geschrieben September 6—ten im Jahr 1799, with three tulips and several colors. Other examples are within easy reach of the writer. And it has appeared evident that the art thus preserved by Mennonites in a remote part of Bucks County until about 1850, and represented by the old paint boxes in possession of the Historical Society, is a survival in America of the mediæval art of manuscript illumination. Much more remains to be said upon this subject which reveals the early relation of Germany to the United States in one of its most interesting aspects.

HENRY C. MERCER.

INDIAN HOUSE, August 30, 1897.

REMARKABLE HAILSTONES.

ABOUT 5 o'clock in the afternoon of August 10th I was at Manassas depot, in Prince William County, Va., near the famous battlefield, waiting for a train. There was some pretty severe thunder and lightning for a half hour or so, and then came a heavy shower of rain, during which there was the most remarkable fall of hail I have ever witnessed. I hurried out in the rain to examine the stones and picked up several. These were nearly square flattish blocks, say from $\frac{3}{4}$ to 1 inch in length and breadth, and from $\frac{1}{4}$ to $\frac{1}{2}$ an inch in thickness. They suggested, by both shape and size, the ordinary 'chocolate caramels,' of the confectioner. There were some 8 or 10 persons, I think, in the station house with me, and several of these, observing my interest and enthusiasm, began to pick up the larger stones and bring them in to me and to to my friend, Professor Hargrove, of Luray, Va. Soon larger and larger ones were thus collected, and I sought for means of measuring or weighing them. No rule or scales could be found, and

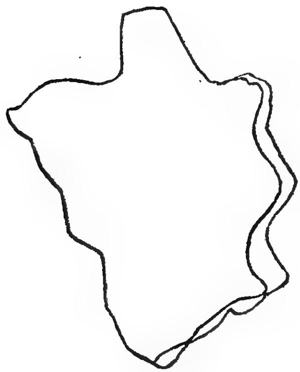


FIG. 1.

FIG. 2.

Outline of Hailstones that fell at Manassas, Va., August 10, 1897.

so we set ourselves, several of us, conjointly and carefully to estimate the dimensions. I recorded at the time one as being, honestly estimated, '2 inches long, $1\frac{1}{2}$ inches wide and $\frac{3}{4}$ of an inch thick,' these being rather the average than the extreme dimensions.

It then occurred to me to make an outline drawing of the largest by laying it flat upon a page of my pocket memorandum and carefully running a pencil around it. I secured, in this way, a rather rough but fairly accurate outline of two. These outlines have been exactly copied (including some lines due to a slipping of the block or to a different inclination of the pencil) and are given in the accompanying cuts. The extreme lengths of these will be found to be, respectively, about $2\frac{1}{2}$ and 3 inches; their extreme breadths about $1\frac{1}{2}$ and 2 inches. The thickness of No. 1 was recorded at the time as being by estimate $\frac{3}{4}$ inch; that of No. 2 as being one inch. I estimate their volumes as about $1\frac{3}{4}$ cubic inches for No. 1 and nearly 3 cubic inches for No. 2. The drawing of No. 2 was done more hastily, as just in the midst of it my train rushed in and I had to leave. But I took my trophy with me, and, with perhaps pardonable enthusiasm, paraded it through the cars, and, exhibiting it to the passengers, asked expressions of opinions from them as to its size relatively to that of a popular object of comparison, a guinea egg. Perhaps 20 or 30 passengers agreed, without dissent, that it was as large or larger. Some said, 'It is as large as a hen's egg;' all agreed, also, that they had never seen so large a hailstone before. Upon breaking it to pieces, I found a sort of nucleus, of somewhat less transparent ice at the center, but observed no concentric layers or other marked structure of any kind; it was quite solid and tolerably transparent throughout. Both of these stones were characterized by blunt points or projections, as shown in the figures; and the sides also, while flat in the main, were uneven with low, rounded elevations and depressions of the same sort, the general thickness being fairly uniform.

I think that very few of these stones or blocks fell. Perhaps they would have been a yard or two apart as they lay on the ground. I think it likely also that the storm of hail was of brief duration, say 10 or 15 minutes, and that it embraced a very limited area.

It was, perhaps, about over when I took the train, as I infer from the fact that I have seen no account of it in the papers; and I found at the next station, only 5 miles off, that the road was dry and dusty.

I regret exceedingly that no more accurate observations seem to have been made of what must have been a most notable hailstorm, and I diffidently submit my own crude and imperfect account in the hope that thereby something further may be elicited in regard to it.

CHAS. H. WINSTON.

RICHMOND COLLEGE, VA.,
August 25, 1897.

THE DEATH OF VICTOR MEYER.

MANY years will pass before Heidelberg entirely recovers from the shock produced by the recent sudden death of Victor Meyer. That so great a man should depart in such a way, and in the prime of his life, seems to be the regret of all who knew his accomplishments.

The work of the semester was practically at an end and the majority of the students had left for the long vacation. It had been a very busy and fruitful period for the department. Every desk had been taken and many applicants turned away. Each student seemed proud of the privilege to work under such distinguished professors, chief among whom was Victor Meyer. His masterly leadership, scholarly attainments and genial manner were the constant inspiration of every one. On the 5th of August he had drawn to a close his annual course of lectures on experimental chemistry. After lingering for a moment to discuss the composition and decay of organic matter, and thanking his listeners for their faithfulness, he left the hall amid deafening and prolonged applause.

Returning from a social gathering rather late Saturday evening, he retired to his room, with the request that he be not disturbed on the following morning. When the door was forced open at noon by the anxious family he had already been dead some time, and the cyanide bottle by the bedside told the story.

When it was first reported that the beloved teacher had died by his own hand, not even his

most intimate friends would believe it, and to many the matter is still an enigma. He seemed too great a philosopher to countenance such an act. It is not improbable that temporary insanity shattered his mind. No expert opinion has been published. Although the fact was seldom noticeable, the great chemist was a very nervous man and had for an extended period been under medical treatment, but without great avail. During the previous winter he was forced to reduce the number of his lectures, but he persisted to the last in assuming all the responsibilities that fall upon a director of so large an institution. The strain was too great. For the last four days he was unable to sleep at all, and the man whose face was still as quiet and pleasant as ever was probably distracted by the fear that the physical forces which had served him so well were threatened with destruction. Only those who have suffered as he did can rightly judge the man. Certain it is that the annoying rumors, circulated by irresponsible reporters, are without any foundation. Of the two letters found on his desk, one expressed his love for his family in most endearing terms. The other was a farewell to his close friend, Kuehne, the famous physiologist.

On account of his expressed wish and because the semester had closed, elaborate ceremonies were avoided. As the quiet assemblage, including many famous scholars, stood around the grave, wreath after wreath was laid at its head. The venerable Bunsen, to whom Victor Meyer went at the age of sixteen to learn chemistry, sent a laurel from his home near by. Adolph von Baeyer came from Munich with a wreath 'to his best friend.' The German Chemical Society paid a tribute to its lost President, and the grand-ducal family of Baden sent a token. Among the many other wreaths was one bearing the words, 'Dem grossen Lehrer in Dankbarkeit, Seine Amerikanischen Schüler.' Heidelberg suffers a great loss, not only as a university, but as a city, for Victor Meyer was a citizen, as well as a scientist, and, while he was profoundly versed in every department of chemistry, he found time to encourage the development of the fine arts.

It is fortunate that there remain such splendid representatives of his school as those who have been his assistant professors. The vacant chair may not be filled for some months. Temporarily the direction of the laboratory is in the hands of Professor Gattermann, who is pushing so rapidly to the front of his science. The other professors, Jannasch, Auwers, Goldschmidt and Knoevenagel are all well-known investigators, and have their own large circles of admiring students.

H. C. COOPER.

HEIDELBERG, August 15, 1897.

THE ANTHROPOLOGICAL SESSION AT TORONTO.

IT may be worth a few lines in SCIENCE to say a word in correction of the many erroneous and even ludicrous newspaper reports of the above meeting which suggest to the memory the famous definition of the crab by the French Academy before it was criticised by Cuvier.

The paleolithic or neolithic age of the New London stone axe was not a subject of discussion, as reported, simply because there was no room for two opinions on the matter. It is beyond all question neolithic, as every archæologist would be ready to assert at a glance.

Nor was any attempt made to prove that American man was older than European man, because again the evidence is so far absolutely conclusive on the other side. The paleoliths of Europe antedate all relics yet known from this continent.

Nor, thirdly, was any attempt made to prove the existence of preglacial man in America. The speakers who claimed the greatest antiquity advocated nothing more than a late glacial date for the oldest traces of human handiwork in this country.

As these three points formed the chief part of many of the reports of the meeting, it is easy to see how far short they fell of correctly representing the speakers.

E. W. CLAYPOLE.

SCIENTIFIC LITERATURE.

THE GENESIS OF THE DIAMOND.

THERE has recently been published a volume of small size, but of especial interest and importance, in regard to the origin of diamonds.

This is none other than the posthumous issue of the full papers of the late Professor H. Car-

vill Lewis, edited by his friend, Professor T. G. Bonney, of London.*

It will be remembered that Professor Lewis was the first to present a clear and definite theory of the origin of the South African diamonds, as resulting from the intrusion of igneous rocks into and through carbonaceous shales, and the crystallization of the carbon throughout the rock as it cooled, from hydrocarbons distilled from the shale that had been broken through. These views, now for the most part accepted, and subsequently confirmed by other and very interesting parallel discoveries, he presented in two papers read before the British Association for the Advancement of Science at its meetings held in 1886, at Birmingham, and in 1887, at Manchester. Before he was able, however, to prepare them for publication and carry them to the greater completeness that he desired, Professor Lewis succumbed to an attack of typhoid fever, which removed one of the most brilliant and capable of the rising scientists of this country. Agreeably to his expressed wishes, his material was entrusted to his friend and co-laborer, Professor George H. Williams, of Johns Hopkins University; but, by a strange fatality, before the latter had time to arrange and edit these papers this distinguished scientist also fell a victim to the same disease, in 1894. The work was then committed to Professor Bonney and is at last given to the scientific world.

The book consists of an introductory note by Mrs. Lewis; a preface by Professor Bonney; the two papers of Professor Lewis himself, with some later notices and references by the editor; a brief account of similar material from other localities, belonging to Professor Lewis—also by the editor; a closing note on some other MSS. of Professor Lewis, and a full index. There are also two plates and a number of smaller illustrations, the latter from Professor Lewis' own drawings.

*Papers and notes on the 'Genesis and Matrix of the Diamond.' By the late Henry Carvill Lewis, M.A., F.G.S., Professor of Mineralogy in the Academy of Natural Sciences, Philadelphia, Professor of Geology in Haverford College, U. S. A. Pages xvi+72. 2 Plates. Edited from his unpublished MSS., by Professor T. G. Bonney, D.Sc. LL.D., F.R.S., &c. Longmans, Green & Co., London and Bombay. 1897.

The first paper, 'On a diamond-bearing peridotite and on the history of the diamond' (1886), is brief, dealing with the general character and occurrence of the diamantiferous rock at Kimberley, and outlining Professor Lewis' theory.

The second paper, 'The matrix of the diamond' (1887), is more extended and goes into an exhaustive discussion and comparison of the various aspects, contents and alterations of the rock, which he finds to be different from any previously described, and, therefore, proposes for it the name of Kimberlite. Its main character is that of a highly basic porphyritic peridotite, filled with olivine crystals and grains, more or less altered, and various other minerals—serpentine, tremolite, etc., with bronzite, rutile, perovskite, pyrope garnets, micaceous minerals and other forms, and at times brecciated in structure, filled with fragments of carbonaceous shale brought up from below. The shales are of Triassic age, the 'Karoo beds' of that region, and the intrusion of the peridotite in the great 'pipes' or chimneys that constitute the mines is therefore proved to be of a later, though not exactly determined period.

The question has sometimes been raised whether the diamonds themselves may not have been carried up from a deeper source in rocks below, instead of originating in the peridotite; and the occurrence of broken crystals has been cited in support of this view. Professor Lewis, however, disposes very completely of this idea in two ways: He refers to the well-known fact that each of the great mines or 'pipes' yields diamonds that have, in some respects, a type of character peculiar to that one and different from the others, so that African experts, and even those who have never been there, can recognize from which mine any diamond has come. Further, as to the broken crystals, he shows that breakage not unfrequently occurs after the diamonds are removed from the rock, and points out that this is a result of strain in their formation, as indicated by microscopical and optical examination, and that such a condition is known to produce ruptures and explosions in other minerals. It may be added here, although Professor Lewis does not speak of it, that many crystals must be broken in the blasting of the rock, the shoveling and the carting

of the loosened material, and the various mechanical processes employed at the mines, and that pieces of such broken crystals would be separated and scattered to various parts of the immense dumping and weathering floors, never to be recognized as fragments of the same one when finally recovered, perhaps at very different times.

The rock itself is a dark green, compact material, resembling serpentine and containing a large proportion of olivine, in grains and crystals; several green minerals that are not conspicuous, from the resemblance of their color to the ground-mass (enstatite, chrome-diopside, smaragdite and bastite); a mica, probably biotite, more conspicuous and quite abundant, and frequent grains of pyrope garnet, sometimes of gem quality and great beauty, and miscalled 'Cape Rubies.' Of smaller disseminated minerals are to be noted perovskite, quite frequent, and magnetite, chromite, ilmenite and picotite, less so, though common. Rare and minute occurrences are apatite, epidote, orthite, tremolite, tourmaline, rutile, sphene, leucoxene. As decomposition products there are serpentine and calcite, abundant, and zeolites, chalcedony and talc; also cyanite (?) These, with diamonds and included fragments of carbonaceous shale, make up the contents of this remarkable rock.

Professor Lewis then goes into a detailed account of the mode of occurrence of these minerals, beginning with the most conspicuous species—the olivine—which is remarkable for its fine cleavage-surfaces and very interesting in its alterations. These are chiefly (1) into serpentine, proceeding from without inward, and penetrating along crevices and fractures, also sometimes in the form of chrysotile, producing a velvety border or coating to the grain; (2) tremolite, more internal, the fibrous structure developing parallel to the vertical axis and domes of the olivine crystals; (3) when both these alterations are present and have gone so far as to obliterate most or all of the olivine, a talc-like substance intervenes between them in which are developed minute needles of rutile, arranged parallel to the faces of the olivine crystal. The rock contains every stage of these changes from pure bright unaltered olivine to those forms that have borders of serpentine or chrysotile, or incipient tremolite fibers within, to the complete alteration just described. The relation of all these to similar phenomena in other rocks, and in meteorites, is discussed with much fulness.

Professor Lewis then takes up the smaragdite, chrome-diopside, bastite and enstatite (or bronzite, for it is just on the line between the two varieties). The two first named are, in some cases, fine enough in color and clearness to yield gems, and also sometimes the bronzite; all are colored by chromium. The diopside occasionally gives rise to calcite by alteration.

The mica is next considered; as all who are familiar with the rock are aware, it is the most prominent of the contained minerals to the eye. It is somewhat anomalous in character, being chemically a biotite, but optically nearer to phlogopite. It occurs in several distinct ways: (1) as included crystalline masses or plates, apparently an original ingredient of the rock; (2) surrounding grains of pyrope; (3) rarely, as a result of the alteration of enstatite; and (4) as a metamorphic product from the included fragments of shale; and the first form has produced, by hydration, the vermiculite variety called vaalite, which occurs freely in the decomposed peridotite so largely known as the 'blue-ground.'

After referring to the pyrope garnets, and suggesting that the various garnetiferous serpentines are doubtless derived from the decomposition of similar peridotites, as further indicated by their likewise containing olivine, bronzite, chrome-diopside, etc., he mentions another variety of garnets as found in this rock, very small, very brilliant, very hard, colorless or greenish, and extremely difficult to distinguish from small diamonds. These Professor Lewis is inclined to refer to demantoid. (?)

An interesting part of this discussion next follows, in relation to the perovskite, which is pretty abundant in small crystals, of cubical habit. Professor Lewis gives much attention, and a number of drawings, to the optical features of this species, and strongly inclines to the view that regards perovskite as a highly twinned orthorhombic mineral and not isometric save in external aspect. This has long been a mooted point, and these observations are an

important contribution. Of much interest also are the chemical and genetic relations of this species as here presented; the crystals often enclose grains of what Professor Lewis terms a titanic spinellid, perhaps a titaniferous magnetite, perhaps ilmenite, indicating a derivation therefrom; they also, in some cases, lie in a curious manner, upon or around partially altered olivine crystals. The remark is made that, while perovskite is familiar in various non-feldspathic igneous rocks, it has not been found in peridotite until Professor Williams recognized it in the peculiar rock from Syracuse, N. Y., and that later Professor Lewis identified it in the similar rock from Isom's Creek, Kentucky, where it had been previously regarded as anatase. These three rocks, those just named and the African, are the only known occurrences of what is here named Kimberlite. The article goes on to show that in basic eruptive rocks the titanium takes the form of perovskite, while in acid rocks it forms sphene; in intermediate ones it develops ilmenite or titanic iron; and these deductions harmonize precisely with important experiments of Bourgeois, in the artificial production of titanium minerals.

After going into some particulars as to the minor minerals found in this rock, Professor Lewis then takes up the base or ground mass and discusses it minutely. He terms it 'a more or less homogeneous serpentinous mass,' very difficult to study by reason of its decomposed condition, consisting now of a mixture of serpentine with calcite and some other products of alteration, the original structure being wholly lost.

Fragmental enclosures are frequent, 'both of the adjoining shale and diabase, and also of more deeply seated granite, gneiss, eclogite, and other related rocks.' Of these the shale predominates, sometimes making the rock a breccia. The shale itself is highly charged with carbon, so as to be quite combustible; but the included fragments are altered, having lost their carbon and become harder, sometimes even metamorphosed to a micaceous structure, as before referred to. In size they vary from large masses, in the upper part of the mines, called by the workers 'floating-reef,' to small fragments, diminishing in number and size in descending.

Professor Lewis goes into very detailed petrographical and chemical discussion as to the original character of the rock, in which it is hardly possible to follow him in a review, and finding no known rock that presents identical characters, he proposes for it the name of Kimberlite. This he designates as 'a porphyritic volcanic peridotite of basaltic structure,' and notes three forms of its occurrence: (1) Kimberlite proper, a typical porphyritic lava; (2) Kimberlite breccia, the same rock broken and crushed by volcanic movements and crowded with included fragments of shale; (3) Kimberlite tuff, the fragmental and tufaceous portion of the same rock. These varieties graduate into each other, and all occur together in the same neck or crater, the second, however, being most abundant and most productive of diamonds.

He treats of the origin of the brecciated structure, which has caused much discussion, some geologists regarding the whole rock as a sort of tufa or volcanic mud, while others hold that it is a true outpouring lava that has carried up fragments of the rocks broken through it its course, and has since been largely decomposed. Professor Lewis urges the latter theory strongly, and supports it by many arguments; while the editor, Professor Bonney, evidently inclines to the other view, advocated by Professor W. H. Hudleston, in 1885, and by some others. There is not space here to review Professor Lewis' several arguments for the true igneous character of the Kimberlite and against the tufaceous theory. The one to which Professor Bonney accords the chief importance is the identity of the rock with that from Syracuse, New York, and Elliott county, Kentucky, where it occurs in actual dikes, such as are not found in tufas. The brecciated character, which is so marked, is referred by Professor Lewis to three causes, acting either separately or perhaps together. These are (1) rapid cooling and shrinkage; (2) 'friction brecciation,' from contact with the wall-rock; and (3) subsequent movements and explosions in the crater itself, below. He illustrates and parallels the first of these from meteorites, to some of which

this rock bears marked resemblance both in structure and contents, and the others from well-known occurrences in terrestrial volcanic rocks.

The third section of the volume is occupied with a detailed account, from specimens and notes of Professor Lewis, of the two other known occurrences of Kimberlite, at Syracuse, N. Y., and Willard, Ky. The identity of these with the African rock, in almost all particulars, is remarkable, and as they form definite eruptive dikes, Professor Lewis' view as to the latter is strongly confirmed.

It remains only to call attention to other and later facts which tend to bear out the views presented in this remarkable posthumous article.

The presence of a residual hydrocarbon in the rock of the African diamond mines was shown by an interesting and important observation of Sir Henry E. Roscoe (Proc. Lit. and Phil. Soc. of Manchester, XXIV., 1885, p. 5), which is alluded to by Professor Lewis in his second paper, and has frequently been cited in discussions of the subject. He found that the 'blue-ground' on treatment with hot water yielded an aromatic hydrocarbon, which he was able to separate by digesting the 'blue-ground' with ether and evaporating the solution. It then appeared as a crystalline aromatic solid, burning with a smoky flame (showing it rich in carbon), volatile, and melting at 50° C.

The bearing of this fact upon Professor Lewis' theory is clear. It indicates that the igneous rock, breaking through the highly carbonaceous Karoo shales (37.50 p. c. of carbon; Whitfield, U. S. Geological Survey; Gems and Prec. Stones North America, 1889, p. 33) became charged with volatilized hydrocarbons distilled from the shale, and that in cooling these had crystallized partly into diamonds and partly into the many carbonadoes, larger and smaller, which are distributed through the rock. Professor Roscoe's material strongly suggests this theory, which, indeed, he himself independently propounded.

In 1886 a meteorite fell at Novo Urei (September 22d) in the province of Pensa, Russia, which was found to contain about 1 per cent. of diamond carbon, in the form of gray particles.*

In 1887 Mr. Fletcher (*Mineralogical Magazine*, 7, 121) described the new mineral 'Cliftonite' —a black substance with a hardness of 2.5 and a density of 2.12, occurring in cubes with faces of the dodecahedron or tetrahexahedron in the meteorite of Youndegin, West Australia. This suggested a graphitic alteration of diamond—a view taken by Brezina (*Ann. Mus. Wien*, IV., 102, 1889) regarding this new species and certain graphitic crystals of cubic type, observed long before in the Arva meteorite and regarded as pseudomorphs after pyrite by Haidinger (Pogg., 67, 437, 1846), but later by Rose, as after diamond (*Beschr. Meteor.*, 40, 1864). Similar crystals were also known in the Sevier iron of Cocke county, Tenn.

In 1891 the discovery of diamond, or at least of diamond carbon, in some quantity in the meteoric iron of Cañon Diablo, Arizona, was announced by the late Professor A. E. Foote (*Amer. Jour. Science*, Vol. XLII., July, 1891, pp. 413–417) and Dr. George A. Koenig. In July, 1892 (Science, p. 15), Dr. O. W. Huntington gave further experiments on the same material, confirming the decisions of Professors Foote and Koenig; and in December of the same year similar results were published by M. C. Friedel (*Bulletin de la Soc. Francaise de Mineralogie*, No. 9, p. 258). A crucial test was then proposed by G. F. Kunz, of New York, and carried out in the presence of Dr. Huntington, at the World's Fair at Chicago, September 11, 1893, viz., the cutting of polished faces on pieces of diamond with some of the carbon powder from the cavities of the Cañon Diablo meteorite (*Amer. Jour. Sci.*, Vol. XLVI., December, 1893; and Min. Resources U. S., 1893, pp. 683–685).

In the meantime Professor Henri Moissan, of Paris, had been making his now celebrated experiments on the artificial production of diamonds from the cooling, under extreme pressure, of highly carbonated iron fused in a specially constructed electric furnace (Mineral Resources U. S., 1895, pp. 903–904).

All these facts taken together form a remarkable series of confirmatory evidence of the views advocated by our late countryman in re-

* Daubreé's discussion of the analogy of the occurrence of the diamond in the meteorites and in the South African Kimberlite was the next important paper on this subject. (Comptes Rendus, 110–18, 1890.)

gard to the production of this most precious of gems, the origin of which has been so obscure a problem in mineralogy and geology. Another point of great scientific interest developed in the course of these investigations is the close similarity, both in composition and in structure, existing between some of these rarer igneous rocks of our globe and the extra-terrestrial visitants that come to us from space.

Mr. G. F. Becker, in a recent letter, takes a different view of this subject and holds that I have misinterpreted Professor Lewis, and that he did not regard the diamonds as due to carbonaceous matter taken up from the shales. He claims that "Lewis over and over again says that the diamond is as much a part of the Kimberlite as its other component minerals." It is true that he did use such an expression of 'the Kimberley rock' (p. 44); but this is in summing up his argument that the diamonds are in their original matrix, as against the early notion of their having been washed into the 'kopjes' from above, or the later theories of their having been carried up with the igneous rock from some deeper source below. The statement relates merely to 'the matrix of the diamond'—the subject of the article—not to the source of the carbon. Moreover, diamonds are not present in the Kimberlite of Syracuse, N. Y., or of Elliott County, Kentucky,* which Professor Lewis recognized as the same rock. He says (p. 56): "In mineral composition, in eruptive character, in structure, in enclosures, the three rocks are identical." It is plain, therefore, that he did not regard diamonds as an essential ingredient of Kimberlite. As to their source being carbon derived from the shales, it is true that Professor Lewis does not in these papers distinctly so assert, though he refers frequently and pointedly to the association of diamonds with the penetrated and included shales. But in personal conversation, at a period between the dates of his two papers, and before he had even heard of the very suggestive experiment of Sir Henry Roscoe, Professor Lewis expressed to the writer his definite belief that such was their origin. The knowledge of this fact may have led me to state this view as held by Professor Lewis more clearly than appears on the face of his paper, and doubtless explains the perplexity that Mr. Becker expresses as to how he and I can read the article differently.

Mr. Becker says: "I consider the diamonds as much a part of the Kimberlite as zircons are a part of granites." This may be Mr. Becker's view; and he is a high authority, with whom I would not lightly disagree; but it can hardly be claimed as the view of Professor Lewis, when he asserts (as above noted) the absolute identity of the diamond-bearing Kimberlite of Africa with the non-diamond-bearing rocks of Syracuse and Kentucky. The question is not whether the diamonds (in Africa) are 'a part of the Kimberlite.' Undoubtedly they are so, there; but how came they to be so at that locality and not at the others? This subject was fully discussed by the writer in 'Gems and Precious Stones of North America,' pp. 32–34, in connection with the examinations made by Mr. Diller and myself in 1887, as to the possible occurrence of diamonds in Kentucky, as suggested by the similarity of the rock. It was there shown that, while the shales penetrated by the African Kimberlite had 37.50 per cent. of carbon, those traversed by the Kentucky Kimberlite contained but 0.68 per cent. The same rock breaks through a body of shale in two localities, the one rich in carbon, the other poor; the intruding rock is fitted with diamonds in the former case and none appear in the latter. And why did Lewis search everywhere for localities where serpentines and peridotites occurred associated with coal formations?

Professor Lewis observes (p. 8): "The rock (at Kimberley) appears in two types, one not bearing diamonds, the other diamantiferous, and the distinction between them is suggestive. Both occur in the same mine and are dark, compact, heavy rocks, closely resembling one another and differing mainly in the fact that one is free from enclosures of foreign substance, while the other is full of fragments of shale and other impurities. It is the latter which is diamantiferous." On p. 46 he notes the fact that the fragments of shale included in the igneous rock have lost their carbonaceous matter; and

* Is there a diamond field in Kentucky? J. S. Diller–G. F. Kunz, SCIENCE, Vol. X., 1887, pp. 140–142.

on p. 51 he cites as of great interest the observation and experiment of Professor Roscoe, elsewhere noted, as to the extraction of a hydrocarbon from the 'blue ground.' These references alone would indicate Professor Lewis' views, even apart from his own statement of them to the writer.

Mr. Becker also alludes to the broken crystals, as repeatedly seen by him in separate fragments enclosed or embedded in the rock, and as not being considered rarities at Kimberley. These occurrences, however, may well be due to the very causes treated of by Professor Lewis in explaining the brecciated character of the rock (p. 54 and above noted), especially the first and third, the latter in particular, 'subsequent explosions and movements in the crater' below. Any such action sufficient to break up the Kimberlite into the likeness of a breccia would easily shatter the highly cleavable diamond crystals and bring about the condition seen and described by Mr. Becker.

It may not be out of place here to recall an instance where, in another locality, the occurrence of diamond may be connected with a similar outbreak of igneous rock through beds containing carbon. In a paper, 'On Bohemian Garnets,' read by me before the American Institute of Mining Engineers, and published in their Transactions for February, 1892, mention was made of a diamond crystal found in 1870 at Dlaschkowitz, Bohemia, among a number of the pyrope garnets which are derived from the decomposition of peridotite rock. After being disputed and identified, it was deposited in the public museum at Prague, where I examined it, as well as the locality where it was found. The decomposed serpentinous rock has evidently been transported from the north (probably by glacial action) and there are found, at a distance of twenty or thirty miles in that direction, basaltic outflows that have broken through the coal measures. Here, again, is a suggestion of similar conditions, and the occurrence of this single crystal is not without interest in such a connection, as may be a Ural crystal at Chitanka, where I identified serpentine and pyrope, but not any carbonaceous materials, as my time was very limited.

It is a matter for national pride that this remarkable investigation should have been made by an American scientist; and a debt of gratitude is due both to the great English meteorologist—the editor, Professor Bonney—for his labor of love, alike to science and to a deceased friend, and also to Mrs. Lewis, who has so carefully sought to prepare and make public these papers of her brilliant and lamented husband.

THE GROUNDWORK OF DYNAMICS.*

The subject of dynamics is too often treated as if its chief value consisted in the opportunities it affords for familiarizing the student with the operations of the differential and integral calculus. It is regarded as a department of applied mathematics rather than of mechanical science. That this should be the case is unfortunate; at the same it is not in the nature of things altogether avoidable. The student cannot afford the time involved in deferring the study of dynamics until he has acquired a working knowledge of the calculus. As a consequence he becomes confused respecting the origin of his difficulties, and possibly attributes to his ignorance of mathematics misconceptions the nature of which may be purely dynamical. It would be of great benefit to him to have the opportunity of attending, before the close of his studies, a short course of lectures on the fundamental principles of the subject, that is to say, the conceptions springing directly from experience, upon which the science is founded. The mind of the individual resembles in its mode of growth the mind of the race. The study of the historical development of mechanical ideas will go a great way in clearing up difficulties which arise from adhering too closely to one line of thought. Many of the greatest advances in science are the result of changes of the point of view. Such changes correspond in some measure with the process known to the mathematician as the transformation of coordinates, a process which often transforms a mass of brain-wearying symbols into ordered groups, instinct with life and

*Address by the Vice-President before Section D. of the Detroit Meeting of the American Association for the Advancement of Science.

meaning. It will be well, therefore, for the student of dynamics occasionally to make the endeavor to transform his coordinates and view the subject from different standpoints. For this purpose it is unnecessary that he should be an expert in refined mathematical analysis. It is requisite, on the other hand, that he should possess, in some degree, what may be called the mechanical instinct. The whole power of modern analysis has not proved sufficient to solve, in its generality, the problem of the three bodies; a problem extremely useful, nevertheless, as an illustration of dynamical principles.

The science of statics, or the laws of composition of forces and couples, was developed from rude experiments made with springs and with strings and weights; the tensions of the strings being measured by the weights. The conditions necessary in these experiments were that the body to which the springs or strings were fastened should be maintained by them at rest, and that all changes of shape and size should have ceased. Statics was thus established without the introduction of the ideas of mass and acceleration. In this stage, however, its laws were supposed to apply only to rigid bodies at rest. The facts to be noted are, that force was recognized as a fundamental conception, and that methods of measuring it and the laws of composition of forces were discovered, without reference to motion except in the respect that rest was supposed to be a necessary condition.

The connections between force and motion, the subject-matter of dynamics, were established by observing the motions of falling bodies, pendulums, bodies rolling and sliding down inclined planes, colliding spheres, bodies connected by strings running over pulleys, etc. In making these experiments it was necessary to know the forces acting. As the only scientific knowledge of force at the time was contained in the laws of statics, the assumption was made that these laws were true, even though the bodies were moving and whether the velocities were increasing, decreasing, or changing in direction. This was a change of the point of view which was fruitful in important results. It was found, however, that while the above assumption was justified in the case of the composition of forces, and in the case of weights when considered as forces acting on the heavy bodies themselves, it was not true to assume that the tension of a string in motion is measured by the attached weight. The true indication of the tension in a string was recognized to be the same as in the case of a spring, viz., the elongation. Again, while in statics, the principal objects were the strings and weights, and the bodies to which they were attached were of little or no account, in the dynamical experiments the bodies assumed importance. The conception of mass was introduced, and was found to correspond with the commercial idea of quantity of material, as determined by the balance and weights. The results of these experiments are contained in the laws of dynamics, or the laws of motion, as they are usually called, which may be summarized as follows:

I. That no change in a body's motion of translation takes place except by the action of external forces.

II. That external forces impress on a body changes of momentum in their own directions at rates proportional to their magnitudes.

III. That action and reaction are equal and opposite, and in the same line.

It seems to be a matter of doubt whether Newton, in his statement of the laws of motion which I have thus paraphrased, intended to affirm that action and reaction are in the same line. Whether there be ground for this doubt or not, the idea is

implied in D'Alembert's principle and is accepted as true.

The third law is a law of force, the value of which is seen when the mutual actions of bodies are to be considered. Without this law the laws of statics and of motion would refer to actions on one body only.

It was evident that the laws of composition of forces could be considered as corollaries of the laws of motion, so that from the latter a more comprehensive view of the measurement of force was gained than from the statical experiments. Thus the statical method of measuring force by balancing the tension of one string or spring against that of another was interpreted dynamically, by assuming that the body upon which the springs acted remained at rest in consequence of receiving from the forces opposite changes of momentum at the same rate. It followed that if the springs were to act singly they would, other things being equal, produce equal rates of change of momentum. Thus dynamics furnished a new method of measuring forces which agreed with that by means of springs.

Further investigation in the light of the new principles showed that the method of measuring forces by weights agreed with the spring measurement and with the dynamical measurement when the condition was observed that the weights were kept in the same locality, but in general not otherwise. Dynamics gave an explanation of this anomaly by showing that the forces of the weights were due to gravity, which evidently might change in intensity from place to place, although the masses of the weights remained unaltered. The measurement of force by weights was thus shown to be a special case of the general dynamical method. Also it resulted that the measurement of force by weights was in principle the same as the measurement by springs, the weight and the earth together constituting a spring whose elastic force is gravity.

It is of little use in the early dynamical training of a student to dwell on the fact that the unit of force in dynamical measure is a force which produces unit acceleration in unit mass. It may even do harm. It may have the effect of leading him to believe that the refined methods of measuring force by means of weights and springs, which are the only methods used in the laboratory, are wrong and that the testing machines and pressure gauges of the engineer are beneath contempt. It ought to be impressed upon him that all the methods of measuring force approved by experience are equally scientific and equally absolute, and will give exactly the same results, aside from unavoidable experimental error, provided that the proper conditions in each case are observed; also that the choice of the method depends, just as in the case of everything else in life, upon the objects in view and the circumstances.

We now come to the period of the development and extension of the laws of motion. While proved in the case of small bodies and motions of limited range, it by no means followed that they applied to the motions of the tides or of the planets. Newton, by the aid of his happy intuition, the law of gravitation, put new meaning into them and extended their jurisdiction over all visible and measurable motions within the solar system.

All motion is, so we are taught, relative; and the motion which is uniform and in a straight line with reference to one set of axes may be varying and in a very crooked line when referred to another set, and perfect rest with regard to a third set. The question then is, for what axes are the laws of motion true? It is very certain that the stresses in the springs by which forces are measured are in no wise affected by the choice of axes of reference.

Imagine a cube of rubber, with several points marked on its faces, and consider the lines joining one of these points with the others. The angles between these lines measure the relative directions of the terminal points from the initial point. Now set the cube in motion ; stresses and strains are generated, in consequence of which the relative directions of the lines undergo small alterations. Why do these changes of direction remain within small limits? Evidently on account of the nature of the material connecting the points.

Consider now another system of points whose relative directions as time goes on remain almost unchanged, viz., the fixed stars. Is it possible that they may be moving like the points on the rubber cube? Observational astronomy indicates that they are at immense distances from the earth and from each other. If the law of gravitation holds for them their mutual attractions must be so feeble that they form a practically unconnected system. The constancy of their relative directions cannot therefore be accounted for as in the former case by the action of the matter between them, but must be attributable to some other cause. The distinction between the two cases, which is very real, is recognized by assuming that a line may have absolute direction; and the stars are said to preserve their absolute directions from the earth. Again, the assumption that both the law of gravitation and the laws of motion are true for the solar system leads to the result (in consequence of its vast distance from the stars) that its center of mass has little or no acceleration; in other words, is either at rest or in uniform motion in a straight line.

Now, although the ideas of absolute direction and absolute rest or uniform motion in a straight line may from the kinematical point of view be incomprehensible, yet in dynamics these terms indicate very definite facts. It is only by the choice of the center of mass of the solar system as origin and by using the stars to fix the directions of the axes that it is possible to make the observed motions of the planets fit, at the same time, the law of gravitation and the laws of motion. It is unnecessary to enter into the details of the work; suffice it to say, it is a process of trial and error, of assumption, computation and check by observation.

The following dynamical consideration enables, in certain cases, a more convenient origin to be used than the center of mass of the solar system.

If equal accelerations are impressed on the bodies whose motions and mutual forces are under consideration, by the attraction of the remainder of the solar system, it is evident that their motions referred to an origin at their common center of mass, with axes fixed in direction by the stars, will be affected only by their mutual actions. Also assuming the laws of motion to apply, these motions so measured will show the whole effect of their mutual actions, since the latter have no effect on the motion of their center of mass. It is thus, possible, in discussing the lunar tides, to use as origin the center of mass of the earth and moon, and in the case of terrestrial bodies the center of mass of the earth. It may be noted that whether the primary origin or such subsidiary origins be used, the equations for the mutual forces under consideration are the same; the effect of the change of origin appearing only in the constants of integration. It will be convenient to term all such sets of axes, including the primary set, absolute axes.

It now remains to determine whether the absolute axes will give results agreeing with those already obtained in the small scale experiments, with axes fixed in the earth; and if they do not, whether the discrepancies can be explained.

If no explanation could be given of such discrepancies it is evident that the science of dynamics would be resolved into a bundle of empirical rules, describing the various axes of reference that applied in different cases, and the range of applicability in each case.

In order to make the comparison, it will be necessary to obtain the data required for transformation from the absolute set of axes with origin at the earth's center, to axes fixed in the earth with origin in the locality of the experiments. These data are furnished by astronomical observations. When the transformation is made there appear on the left-hand side, let us say, of the equations the rate of change of momentum of the body relative to the axes fixed in the earth, and on the right-hand side the attractions, tensions and other impressed forces, together with certain terms involving the relative motion of the two sets of axes.

In the equations of the original experiments no terms of the latter kind occurred. There are three ways of accounting for the difference. Either the forces are different in the two sets of equations, or the new terms are so small as to be within the limit of experimental error, or each experiment or class of experiments requires its special set of axes.

Experience shows that the explanation lies in the first or second alternative; the the third is not true.

These terms are generally negligible in laboratory experiments. It is necessary to consider them in the theory of winds and ocean currents. Their presence in the equations has suggested certain experiments with pendulums and gyrostats, which confirm their truth. We are justified by experience, for instance, in believing that in the northern hemisphere moving bodies tend to the right, in the southern hemisphere to the left; bodies moving eastward tend to rise, westward to fall; and that bodies, whether at rest or in motion, tend to move outwards from the polar axis. All such tendencies are represented by the terms under consideration. They may be regarded when written on the force side of the equations as representing relative or fictitious forces; fictitious because they correspond to no actions of matter, but are the consequence simply of the motion of the axes of reference relative to the absolute axes.

Sometimes it happens, as has been indicated, that the discrepancy lies in the fact that the forces in the two sets of equations are different, although referring to the same experiment. Consider the case of a body suspended from a spring. Referred to axes fixed in the earth it is at rest, and the inference is that the attraction of the earth is equal and opposite to the tension of the spring. Referring, however, to the same axes by transformation from the absolute axes, there appears, in addition to the terms representing the tension of the spring and the attraction of the earth, a new term, a relative or fictitious force, known as the centrifugal force. The inference now is that the attraction of the earth is greater than the tension of the spring, instead of being equal to it. If this inference be accepted as the true one the question arises, which of the original forces was wrong, or were both astray? Remembering that the intrinsic indication of the force exerted by the spring is its elongation, and that of attraction the acceleration caused by it, also that acceleration depends on the choice of axes of reference, while the elongation of a spring does not, there can be no hesitation in deciding that the error lay altogether in the estimate of the attraction. The fictitious force, while itself invisible, also rendered invisible a portion of the earth's attraction. By using proper axes of reference its true character is revealed and

its power for evil destroyed. If the mechanism of attraction were not concealed, or if it had some distinguishing mark other than acceleration, and it were possible to experiment with it as with springs, such an error could not be made, even with improper axes of reference.

A convenient way of regarding the laws of motion is to consider, as before, the second law as affirming the relation between force and change of momentum, and the third and first as asserting the principle of conservation of momentum; the third implying that momentum passes from one body to another without change, and the first that the only way by which the momentum of a body can suffer alteration is by part of it passing into another body. Again, if it be assumed that the third law implies that action and reaction are in the same straight line the principle of the conservation of angular momentum will follow.

The statement is sometimes made that the 'bodies' of Newton's laws must be regarded as particles. I cannot take this view; they are real bodies, of all sizes, and with all the qualities known and unknown of such bodies. They are not the imaginary bodies of the mathematician, the dramatis personæ of the algebraic theatre, possessing only the qualities arbitrarily assigned to them for the special purpose of the investigation in hand.

The laws of dynamics thus hold for all bodies within the solar system whose masses, forces and motions have hitherto been observed and measured; but the motions must be measured with essential reference to only one set of axes, namely, a set whose origin is in the sun and whose directions are fixed by the stars.

Kinematics deals with relative motion; Dynamics with the 'Motus Absolutus' of the Principia.

We now pass to the consideration of the laws of energy in their dynamical relations.

In the discussion of statics as the forerunner of dynamics, attention was directed mainly to the springs and strings and weights by which the forces were measured. The original statical experiments may also be regarded as the source of the principles of energy in connection with mechanical science. From this point of view the bodies upon which the forces act come into prominence, not because of their masses as in dynamics, but on account of their shapes, sizes and rigidity. Thus the experiments were made with levers, pulleys, inclined planes, wedges, etc.—in fact, with instruments for doing work, the mechanical powers of the text-books. In the statical principle of virtual velocities we have the origin of the principle of the equivalence of work and energy. To men of all times the most natural way of regarding force has been, as the action by which material is stretched, bent, twisted, broken or displaced, *i. e.*, whereby work is done. Even the word momentum, in the language of ordinary life, implies the power of doing work. It is worth consideration whether it may not be better in the instruction of students to work up to the ideas of dynamics through elementary examples of the equivalence of work and kinetic energy, rather than by taking the ordinary balloon passage to the laws of motion. While less systematic and formal, this procedure would be more natural and probably more useful.

The laws of energy may be summarized as follows. When work is done on a body an equivalent amount of energy is partly transformed and partly transferred without transformation. It is in general partly transmitted to other bodies with which the given body may be in physical connection. Its transformations are into stored energy and dissipated energy. Examples of stored energy are the potential energies due to gravitation, the forces of elasticity, magnetic and electrical attractions and

molecular forces. Such forces are termed conservative. Kinetic energy is another form of stored energy. Energy is dissipated by means of the forces of viscosity and friction, known as dissipative forces. Energy is also stored and dissipated in certain electrical, electro-magnetic, thermal, chemical and other actions which have not been identified with force and which, therefore, are not dynamical.

In order that work may be done there must be a source of energy, or place from which it comes, and a sink, or place to which it goes, together with an energy stream from the source to the sink. When work is done continuously the energy stream is accompanied by a circuit or system of stored energy which acts automatically as a moderator of its fluctuations.

The principle of conservation affirms that energy can neither be created nor destroyed, so that its changes are changes in form but not in amount.

The principle of the equivalence of work and energy is analogous to the second law of motion, considered as expressing the equivalence of impulse and momentum; that of the conservation of energy has its analogue in the third and first laws of motion regarded as affirming the conservation of momentum.

Newton notices this analogy in his scholium to the laws of motion in the words, "just as bodies in cases of collision have the same effect, whose velocities are inversely as their masses, so in putting machines in motion agents have the same effect, whose velocities in the directions of their forces are inversely as these forces." The now well known reference in the same scholium to the action of machines, the importance of which was pointed out in Thomson and Tait's Natural Philosophy, was in continuation of the same line of thought.

The impulse or time integral of a force is fully accounted for by the change of momentum, while the work or displacement integral is only partially accounted for by the change in kinetic energy, in all cases of real bodies. The reason for the difference is that the laws of motion are a complete statement of our experience of force in relation to the motion of a body as a whole, *i. e.*, the motion of its center of mass. On the other hand, the laws of energy require the consideration not only of this motion, but also of all internal motions and forces.

The principle of the equivalence of work and energy is a statement of an effect of force essentially different from its effect in producing change of momentum. It might be supposed, therefore, that this principle would be useful in affording another means of measuring force. The impossibility, in general, of measuring the whole change of energy due to an unknown force acting through an observed distance renders this idea to a great extent fruitless. If the laws of energy are true such a method of measuring force must give the same result as the dynamical method. The measurement of force by springs is based on this principle, and not on the second law of motion. Although no attempt is made to measure the change of energy due to the work of extending a spring, yet experience goes to show that the energy changes due to given extensions made in the same order are constant, and hence the corresponding forces are constant.

The connection between the laws of energy and those of motion may be stated as follows: Energy and work, like force, are fundamental conceptions gained from experience and having various relations with phenomena which can be discovered only as a result of experiment and observation. One of these relations is that work is proportional to the product of force into displacement. This relation is, therefore, a natural law, of the same order of impor-

tance as the second law of motion, and not a mere verbal definition. Experience thus gives a dynamical measure of work as well as of force.

The law of equivalence of work and energy then establishes work as a dynamical measure of energy.

The laws of motion, combined with this law of energy, establish the result that kinetic energy is proportional to the product of momentum and velocity, and thus furnish a dynamical method of measuring energy in its kinetic form. This is the sole contribution of the laws of motion to the science of energy.

It is only in the case of bodies whose internal forces and motions are known, or determinable from assumed data, in other words, imaginary bodies, that the laws of energy, as far as they are considered in dynamics, are included in the laws of motion and therefore become unnecessary, except for the purpose of convenience in mathematical analysis, or economy of thought. Even in such cases the expressions for work and energy retain a flavor of their original meaning and do not altogether degenerate into mere mathematical symbols.

The science of dynamics, as it is understood at the present day, includes among its fundamental principles, in addition to laws of motion, the principle of the equivalence of work and energy, and the principle of the conservation of energy; energy being measured, however, only in terms of force and displacement, or momentum and velocity.

The only actions known in dynamics are force and its integrals, impulse and work. To identify with these all other actions involving the transfer and transformation of energy, such as the conduction of heat, chemical reactions, induction of electric currents, etc., forms to-day the severest task of mathematical physics.

JOHN GALBRAITH.
SCHOOL OF PRACTICAL SCIENCE, TORONTO.

MATHEMATICS AND PHYSICS AT THE BRITISH ASSOCIATION.

MEETING this year at Toronto in the week immediately succeeding the meeting of the American Association at Detroit, the British Association had the advantage of securing the attendance of a number of distinguished American scientists, who added greatly to the strength and interest of the proceedings. Taking Section A alone, it is sufficient to mention the names of Dr. Hill, Professors Michelson and Newcomb, as Vice-Presidents; and of Professors Barker, Carl Barus, Bedell, Carhart, Merritt, Nichols, Rosa, and many others who attended the meetings and assisted at the discussions in the work of the Section.

It is generally conceded, even by the rival sections, that A is not only the first but also the most strongly represented section, if not always in the number of its rank and file, at least in the distinction of its leaders and in the vigor and extent of its work. This year, in spite of the distance from home, formed no exception to the rule. Although some familiar faces were absent, the section formed a very strong and representative gathering of mathematicians and physicists. There were no less than fifty names on the committee, but it would have been easy to add to this number without going beyond the list of those attending the meeting whose work was already known.

In many ways, the extremely varied interests which the Section A represents are doubtless a great element of strength, but there are certain drawbacks in its excessive vitality. It brings together men from a number of different but closely allied departments of knowledge, who, if they did not possess some such common meeting ground, would be less able to keep in touch with each other, and to assist in the general advancement of science. At the same time it cannot be denied that the section is somewhat overburdened with an excess of com-

munications which are too good to refuse, and that in consequence of the press of work and of the extremely mixed character of the audience, the discussions on the various papers, which should be the most valuable and interesting part of the proceedings, are generally of a very perfunctory and almost casual order. Similar considerations lead to the curtailment of the papers as well as of the discussion. Many of the authors are influenced by an undue regard for the feelings of the more popular part of the audience, and are thus impelled to omit technical details of the highest interest and importance for the due appreciation of their work by those competent to judge.

Upwards of 60 communications, out of many more that were sent in, were accepted and read in the course of the five days on which the section met. In order to get through this program, it was necessary to sit till 3 p. m., on many of the days, without any intermission for lunch. On two of the days the section divided into two departments, Mathematics and Meteorology on Monday, Electricity and General Physics on Tuesday. This plan has been found to work well in previous years, but is not without its defects. Professor Rosa, for instance, was engaged in reading a paper in one department at a time when another of his communications was due in the other. He was thus compelled to miss the reading and discussion of a number of papers closely allied to the subject of his second communication, and those present in the electrical department were compelled to miss the description of his most ingenious and complete electrical calorimeter as applied to the verification of the law of conservation of energy in the human body. Under any system of subdivision, it is probable that similar difficulties must occasionally arise, but the question is now under the consideration of a special committee, and it is hoped that some more perfect arrangement may be evolved in time for the next meeting.

An audience of over four hundred assembled in the Chemical Lecture Theatre to hear the address of the President, Professor A. R. Forsyth, who succeeded Cayley in the chair of pure mathematics at Cambridge. His address was an eloquent and convincing vindication of the importance of studying mathematics for its own sake with the single aim of increasing knowledge, and not, as some would have it, from a utilitarian point of view, as an instrument for the use of the engineer, the physicist or the astronomer. The path of practical utility, as he justly remarked, is too narrow and irregular, not often leading far. It is evident from the demeanor of the audience that they were all thoroughly interested and engrossed in the subject of the address, which, it is to be hoped, may do something to moderate the utilitarian and technical spirit, and to check its inroads upon the sanctuaries of university education.

The ventilation of the Chemical Lecture Theatre appears to have been overlooked in its construction; but, in spite of a somewhat asphyxiating atmosphere, the larger, and, we may also say, the wiser part of the audience, remained behind to hear the presidential address of Professor Ramsay to the Chemical Section, on 'An Undiscovered Gas.' Professor Ramsay is a physicist no less than a chemist, and his search for the undiscovered member of the triad of which helium and argon are the extremes, raised many questions of the widest general interest to the physicist as well as to the chemist. The methods which he was compelled to adopt in treating these substances, which have no chemical properties, were also physical rather than chemical, depending on differences of density, refractivity, and rate of diffusion. Helium appears to be unique among elements in possessing an extremely low refractivity in proportion to

its density. The physical methods of diffusion, and of measuring and comparing the refractivities of different gases and mixtures of gases, appear to have been carried to the highest degree of refinement which has yet been obtained, in this nominally chemical research.

After adjourning to the Physical Lecture Theatre, the section took up the ordinary business of the meeting. A paper was read by J. A. Paterson, 'On the Unification or Time,' a question of considerable interest to Canadians. In the discussion, it was pointed out by Professor Rucker that, for the present, international agreement was hopeless. The question had recently been considered by an influential committee of the Royal Society, who had decided that the present was not a suitable time for action. A committee was subsequently appointed by Section A to consider what action could be taken in the matter.

Professor Rucker, assisted by Forsyth and Sowter, showed some photographic records which had been obtained of objective Combination Tones, which were of great interest in connection with certain disputed points in the theory of such tones.

The report of the Committee on Seismological Observations was read by the Secretary, Mr. J. Milne. Among the points specially discussed were the greater frequency of sub-oceanic disturbances as compared with land-quakes, the large number of such movements originating in Tuscarora Deep being taken as a special example. It had also been shown by means of observations of earthquakes taking place in various parts of the earth, and registered by means of one of Milne's horizontal recording pendulums for unfelt earth-movements, that the velocity of propagation of such movements was much higher through the lower strata. The nearer the path to the center of the earth, the higher the velocity. By means of several of these instruments, which are now being set up in different parts of the globe, it is hoped to obtain important information with the regard to the interior constitution of the earth. Such records have also been proved to be of great practical utility in connection with the breaking of submarine cables, and other effects of suboceanic disturbances.

On Friday a paper was read by Dr. N. E. Dorsey, 'On the Determination of Surface Tension by the Method of Ripples.' Dr. Dorsey had applied the method used by Lord Rayleigh with great refinement to the measurement of the surface tension of water and of dilute aqueous solutions. He found that the surface tension was approximately a linear function of the concentration.

Professor H. L. Callendar and H. T. Barnes, of McGill College, Montreal, described their new method of determining the 'Specific Heat of a Liquid in terms of the International Electrical Units.' The practical details of the method have already been completely worked out, and several sets of observations have been taken in the case of water and mercury. The method consists in passing an electric current through a current of liquid flowing in a fine glass tube enclosed in a glass vacuum jacket, which is exhausted as perfectly as possible, and then hermetically sealed. The electric energy is measured by the potentiometer method in terms of the Clark cell and the Standard Ohm. The heat generated is measured by observing the flow of liquid and the steady difference of temperature between the ends of the fine tube. The time of flow is automatically recorded on an electric chronograph on which a standard clock is marking seconds. The difference of temperature is given by a single reading on a pair of differential platinum thermometers.

The method was primarily devised for the purpose of investigating the question of

the rate of variation of specific heat with temperature, which could be determined independently of the absolute value of the Clark cells used in the work. It is also of special interest in connection with the recent proposal of the Electrical Standards Committee of Section A to adopt the Joule or Watt-Second as the absolute unit of heat. According to the most recent reductions, the result of Rowland by the mechanical method, and of Griffiths and Schuster by the electrical method, for the specific heat of water differ by about one part in 400. This discrepancy is possibly due to an error in the value assumed for the Clark cell, but it is interesting to verify the comparison by a totally different method of calorimetry, to avoid any possible errors which may have remained unsuspected in the ordinary method, in which a known mass of water is heated through a certain range of temperature. In the method of Callendar and Barnes the temperature conditions are extremely steady, and observations can be taken under the most favorable conditions. The external loss of heat is reduced to a minimum by means of a vacuum jacket, and can be very accurately measured by varying the electric current and the flow of liquid in a suitable manner. Since there is practically no change of temperature, the correction for thermal capacity of the calorimeter is negligible.

A crowded audience assembled to hear Lord Kelvin on the 'Fuel and Air Supply of the World.' The address, which lasted about half an hour, was very characteristic, especially in the humorous attack on the English system of measures. Assuming that the earth was originally at a high temperature, and that there was at first no free oxygen in the atmosphere, it may be concluded with a high degree of probability that the present store of oxygen has been evolved by the action of sunlight on vegetation. To every three tons of oxygen there corresponds on the average one ton of coal or of fuel derived from vegetation. As there are at present two tons of oxygen to every square meter of the earth's surface, the total oxygen supply may be estimated at about one thousand million million tons, and the total fuel supply at 340 million million tons. According to the estimates of the Coal Supply Commission of 1831, it appears that England, with an area equal to one two-thousandth part of the earth's surface, possesses more than its share of fuel, the greater part of which is available for working. As the coal is used up, if it were not for increasing vegetation, we should be more likely to die from want of air than from want of coal.

Dr. Alexander Johnson, of McGill College, followed with a plea for an Imperial Hydrographic Survey. A committee of the British Association appointed at his suggestion in 1884 had succeeded in inducing the Canadian government to make a grant for the promotion of tidal observations. This grant has recently been reduced, and there was some risk that it might be discontinued altogether at a time when such observations were of special importance. At Professor Johnson's request an influential committee was again appointed to seek the cooperation of the Admiralty in establishing a permanent department.

Professors Ewing and Dunkerley, of Cambridge, England, contributed a paper on the 'Specific Heat of Superheated Steam.' They adopted the method of the throttling calorimeter, which is not so well known in England as in America, but instead of determining the wetness of the steam in terms of the degree of superheating observed they used a separator, and assuming the steam to be dry, deduced the value of the specific heat. A roll of silk was used, following Thomson and Joule, instead of an aperture for throttling the steam.

Professors Runge and Paschen contributed a note in continuation of their well-

known spectroscopic investigations. They find that the spectrum of oxygen consists of six series of lines, two principal groups each with two subordinate groups, having harmonic relations to each other. The spectrum of oxygen is thus analogous to that of helium. At one time it was supposed that this character of the spectrum might indicate that the substance examined was really a mixture of two different elements closely resembling each other in properties. Many elements, such as sodium and lithium, give only one series of lines. This hypothesis has, however, been recently abandoned.

W. J. Humphreys next read a paper on 'Changes in the Wave-Lengths of the Lines of Emission Spectra of Elements.' The changes examined were caused by increasing the pressure of the air surrounding the electric arc up to six or twelve atmospheres, which was found to produce a shift of the line towards the red end of the spectrum, the amount of the shift being nearly in direct proportion to the pressure, and never exceeding a tenth of an Angstrom unit for the pressure employed. The shifts were in general proportional to the wave-length, but different series of lines were differently shifted. Shifts of similar lines of different elements are said to be inversely as the absolute temperatures of the melting points of the substances, proportional approximately to the products of the coefficients of linear expansion of the solid and the cube root of the atomic volume. The effect is, therefore, like the atomic volume, a periodic function of the atomic weight. It is considered that some of these relations may be accidental, as most of the time was spent in measuring the lines and not in hunting after empirical relations.

In making the measurements, the best spectroscopic equipment of the Johns Hopkins laboratory was used. Besides a number of eye observations, several hundred photographs were taken, and almost every known metallic element examined. The shifts due to pressure may be distinguished from those due to the Doppler effect, because different lines of the same element are differently shifted, and the direction of the shift is always to the red. The largest shift observed would correspond to a velocity of recession of some four miles a second.

A communication from Professor Schuster, 'On the Constitution of the Electric Spark,' described measurements of the velocity of translation of metallic particles in the spark. The velocity found was from 400 to 2,000 metres per second.

Professor S. P. Thompson showed some experiments on varieties of cathode rays, which he classified according to their powers of exciting X-rays, of producing fluorescence, and of being deflected or not by a magnet. The ordinary cathode rays after reflection from the anticathode were found to be still fluorescifiant and deflectable, but to have lost their power of exciting X-rays. A third variety was produced by passing the cathode rays through a negatively electrified spiral or sieve, which changed the nature of the fluorescence and rendered them non-deflectable. A fourth variety was found in the funnels of a Holtz tube. Under the hurried conditions of the section meeting, it was not very easy to follow and observe these several effects.

Among the other papers on Friday were two by Professor S. P. Thompson, on a 'Tangent Photometer,' and on an 'Experiment with a Bundle of Glass Plates.' There were also two important contributions from John Hopkins on the comparison of the thermometers used by Rowland in his determination of the mechanical equivalent of heat (1) with the Paris Hydrogen Scale, and (2) with the scale of one of Callendar and Griffiths' platinum thermometers. The results of these experiments were to show that, when reduced to the same thermometric scale, the results of Rowland for the

rate of variation of the specific heat of water were in agreement with those of Griffiths, but there was a difference of about one part in 400 in the absolute value at any point. This point was particularly referred to in the Report of the Electrical Standards Committee, and it was suggested that the discrepancy might be due to an error of 0.1 % in the assumed value of the electro-chemical equivalent of silver.

The last paper read was by Professor H. L. Callendar and N. N. Evans, 'On the Behavior of Argon in X-Ray Tubes.' The authors had expected to find that pure argon, in consequence of its inertness and its supposed monatomic character, would give a very constant vacuum in such tubes. They found, however, that if the gas were very carefully dried, the resistance of the tube increased very suddenly, and the electrodes were melted or spattered over the walls as the vacuum approached the X-ray stage. The presence of residual hydrogen appeared to be necessary to enable the discharge to pass from the cathode to the gas. These effects were substantiated by experiments with other gases.

On Saturday the majority of the members dispersed on excursions to Niagara and various other places of interest, and with the exception of the Geological Section there were no meetings.

On Monday the section divided into two departments, Meteorology and Mathematics, and those specially interested in electrical work repaired to Section G, which devoted itself on this day to electrical questions. In the meteorological department papers were read by John Hopkinson 'On Monthly and Annual Rainfalls at Ten Stations in the British Empire, 1877 to 1896.' It appears doubtful, however, whether so listed a series of observations can be taken as representative of the pluviology of the Empire. By Dr. Van Rijckevorsel 'On the Temperature of Europe.' From certain peculiar maxima and minima exhibited by the curves of daily temperature, he considers that the continent may be divided into two regions in which a different type of weather prevails. R. F. Stupart, the Director of the Meteorological Service of Canada, contributed a paper on the 'Climatology of Canada.' F. Napier Denison, from a comparison of simultaneous records of changes of level in the Great Lakes and of smaller undulations in the atmospheric pressure by by means of a sensitive barograph, concludes that the larger differences are due to difference of atmospheric pressure over the extremities of the lake, but may be greatly augmented by the action of the wind on the surface of the water. The smaller undulations appear to be due to atmospheric waves caused by currents in different strata traveling in opposite directions, as shown by Helmholtz. Papers were also contributed by Rotch and Marvin 'On the Exploration of the Air by Kites,' showing how it was possible by means of recording instruments, sent up to great elevations attached to a kite to obtain information with regard to the temperature and hygrometric condition of the air, which would be of use in forecasting. It would appear, however, that there is still much to be done in improving the recording hygrometer.

In the department of mathematics there were several papers of esoteric interest. Alexander Macfarlane made an application of hyperbolic analysis to the solution of the cubic equation. Dr. Harris Hancock discussed the history of the Abelian Functions. Professor O. Henrici proposed a convenient notation in Vector Analysis, upon which it would be difficult to express an opinion without extended use by different workers and authorities in the subject. Professor Michelson and A. W. Stratton described some new Harmonic Analyses, in which they had succeeded in carrying the process as far as 80 terms. Papers were also contributed

by Major MacMahon on 'Partitions of Numbers;' by J. C. Glashan on the 'Quinquisection of the Cyclotomic Equation,' and by Dr. Larmor on 'Jacobi's Last Multiplier.'

On Tuesday the section divided along the lines of Electricity and General Physics, and many members regretted that they were unable to be present in both sections simultaneously. In the electrical department there were a number of papers on electrical waves and oscillations of different forms. Professor Braun showed how, by the action of a magnet on a small pencil of cathode rays directed on to a fluorescent screen, it was possible to demonstrate the form of the wave, either by developing the oscillating line of light into a curve with the aid of a revolving mirror or by using a second magnet to give the corresponding Lissajou figure. The frequency of the coil used was not, however, suitable to show the effects in a sufficiently clear manner to an audience. Professor Rosa exhibited an extremely ingenious mechanism for automatically plotting the form of an alternate current wave by the periodic contact method. At each point of the cycle the instantaneous difference of potential to be measured was found by shifting a contact point on a potentiometer wire till the galvanometer indicated a balance. On depressing a key the point so found was recorded on a cylinder, which was moved forward automatically in step with the periodic contact brush on releasing the key. By this means from twenty to thirty points could be recorded in a minute. The curves exhibited showed in a very remarkable manner small waves due to armature teeth and commutator segments, which could not be obtained with any slower method, owing to the necessarily limited number of points. Taking special precautions to secure very steady running of the machines, he had been able to analyze these curves with great accuracy as far as the fifteenth term of the harmonic series.

W. D. B. Duddell exhibited an instrument of a totally different character which could be applied to secure instantaneous photographs of the forms of these curves even under conditions of rapid change such as occur in studying the alternate current arc. He had succeeded in so reducing the period and adjusting the damping of a galvanometer with a pair of strips stretched between the poles of an electro-magnet and immersed in oil, on the plan suggested by Ayrton and Mather, that he was able to obtain very beautiful records of current and potential simultaneously at the ordinary rates of alteration on a falling plate. So far as could be judged from an inspection of the numerous specimens shown, the effect of inertia was practically eliminated. It would not, of course, be possible to measure the these curves with the same degree of accuracy as those obtained by the point-to-point method, but instantaneous photographs can be secured in cases where the slower method would be totally inapplicable.

After the reading of the Report of the Committee on Electrical Standards, to which reference has already been made, Professor J. V. Jones explained a method of calculating the coefficient of mutual induction of a circle and co-axial helix, by which the labor may be considerably shortened. This calculation is required in the Lorenz method of determining the ohm. Professor Ayrton next gave an account of the experiments in which he had been engaged with Professor Jones in redetermining the ohm by means of the Lorenz apparatus constructed for Professor Callendar, of McGill University. This apparatus has been made by Nalder Brothers, under the personal supervision of Professor Jones, and is considered to be the most perfect apparatus of its kind. The value found for

the ohm was nearly one part in 2,000 smaller than that usually accepted, but the uncertainty of the measurements was due rather to discrepancies in the comparisons of the standard coils than to want of consistency in the readings given by the instrument.

Professor Ayrton also communicated a paper by Mrs. Ayrton on the 'Relations between Arc Curves and Crater Ratios with Cored Positive Carbons,' which is being published elsewhere. Mrs. Ayrton is well-known as an authority on these subjects, but the paper is one which cannot be adequately explained without the curves by which it was illustrated. Papers were also contributed by Cerew and Basquin, 'On the Arc;' by Willard E. Case, on 'Gas Batteries,' and Professor J. C. MacGregor, on the 'State of Ionization of Solutions.'

In the department of general physics, there were a number of interesting papers on acoustics and on astronomical and magnetic observations, but the writer was unable to obtain any adequate abstracts or reports.

On Wednesday, Professor Ramsay read a paper on the refractivity of mixtures of gases. According to his observations, the refractivity of a mixture could not be deduced by the usual mixture formula. The discrepancy between theory and observation in the case of a mixture of hydrogen and helium amounted in some proportions to as much as 3%, with oxygen and nitrogen to 0.35%. These differences were systematic, and appeared to be too large to be due to observational errors. They indicate that the refractivity is not accurately proportional to the partial pressure, but that there is a deviation analogous to the deviations from Boyle's law, and apparently in a similar direction. It must be remembered, however, that the refractivity of helium is so phenomenally low as to make these measurements extremely difficult.

Professor O. Lodge introduced a discussion on 'Zeeman's Discovery of the Effects of Magnetism on Spectral Lines.' These effects have been recently described in a communication by Professor O. Lodge to the Royal Society of London, but it would appear from the discussion which took place in Section A, that the effects are so small even in the strongest fields, and are so difficult of study, that the physical explanation of the effect is still a matter of speculation.

Professor Ayrton communicated three papers by himself and J. Mather, on the use and sensibility of galvanometers, a subject upon which they are universally recognized as leading authorities. He explained the principle of the constant total current shunt, as applied to ballistic galvanometers, proposed a standard method of measuring the sensibility, and discussed the question of short versus long-period galvanometers for very sensitive zero-tests. He also exhibited a very simple and sensitive galvanometer of the D'Arsonval type, with a coil resistance of only 1.9 ohms, time of complete oscillation 7.5 secs., which gave a deflection of 36 millimetres at 2 metres for one microvolt.

A paper on the comparison of certain Thermocouples with the platinum resistance pyrometer was read by Mr. H. M. Tory, of McGill College. He showed that the parabolic formula could be regarded only as a rough approximation to the law of variation of the E.M.F. of a thermocouple. Using a platinum-rhodium couple enclosed in the same tube as the platinum pyrometer, he obtained very consistent results up to 1,000° C., showing deviations from the parabola of the same type as with the copper-iron couple at low temperatures. He showed that the assumption of a straight-line formula for the platinum-rhodium couple, which is often taken as sufficiently correct, may lead to errors of the order of 100° C.

Professor Callendar read a paper by himself and H. T. Barnes, of McGill College, on

'A Simple Modification of the B.O.T. Form of Standard Cell.' In this cell the usual construction is reversed, and the materials are introduced in the inverse order, namely, zinc amalgam, sulphate of zinc crystals, mercurous sulphate paste, platinum wire. The cell is portable and free from diffusion-lag, and is much easier to make and more convenient to use than the H-form. Owing to its shape, which permits of immersion in a water-bath, it is more suitable than the H-form for very accurate work, in which an exact knowledge of the temperature of the cell is required. The same construction is also applied with equal facility to the cadmium cell, but it appears that the latter cells are less consistent than the Clark cells at temperatures between 0° and 10° C.

There was a general consensus of opinion that the meeting had been as well up to the average in the quality and quantity of the work submitted, as it had been thoroughly enjoyable and successful from a social point of view. With so many communications to get through, it is to some extent inevitable that the discussions should be curtailed, but the authors of papers are themselves chiefly to blame in many cases if the discussion appears inadequate. It may be possible in future years to exact more stringently that the author should submit an intelligible abstract in advance, which might be obtainable at an early hour on the day on which the paper is read. In the few cases in which the printed abstracts are available they are frequently allowed to lie on the table, and were of no practical assistance to the discussion, as no one knew of their existence. It is to be hoped that the wide range of the work of Section A will not be allowed to detract from its usefulness, and that the committee appointed to consider the question will succeed in devising some scheme of departmental organization to mitigate the overcrowding of papers in future.

HUGH L. CALLENDAR.

THE BOTANY OF THE BRITISH ASSOCIATION.

THERE are few opportunities when it becomes possible for the botanists of America and Europe to exchange views and gain that personal knowledge of co-workers in which lies the real essence of acquaintance among scientific men, beyond those afforded by individual effort. It is true that a large number of American botanists have prosecuted more or less extended studies abroad, both in England and on the continent, and this number appears to be annually increasing. The majority, however, are denied such privileges, and for them it becomes a matter of first importance that occasions should arise when they are able to gain direct acquaintance with those who have been known to them in other ways for years. In 1884 the British Association for the Advancement of Science departed from its time-honored custom and held its first colonial meeting at Montreal. So rare an opportunity was eagerly taken advantage of by a large number of representative botanists from both sides of the Atlantic, and, although it was impossible at that time to fully measure the value of the results to be obtained, it was nevertheless felt that the work accomplished must be productive of great benefit, not only in a general advance of botanical science, but in a far better understanding between the botanists of Europe and America. The lapse of years has fully justified this view, and when it was announced that the British Association intended once more to visit Canada, after a period of thirteen years, the prospect was generally hailed with delight by American botanists, who would gladly see these opportunities for scientific conference become more frequent.

The sixty-seventh annual meeting of the British Association, recently closed at Toronto, will be remembered as a notable one in the history of botanical progress on this side of the Atlantic. The great ac-

tivity and interest which centered in the Botanical Section were largely due to the able and energetic manner in which the President conducted the work in hand. To the botanists of the United States, however, is also due no small credit for their share in this happy result. The determination had evidently been reached on their part to make the botanists of Great Britain feel that, although they were to be within their own domain during the progress of the meeting, there is a brotherhood in science which ignores all geographical and political limitations, and that on these grounds the most cordial sympathy and support should be extended. This was made evident not only in the very fortunate arrangement whereby the Botanical Society of America met at Toronto instead of at Buffalo, and concluded its proceedings as the work of the British Association began, but also in the fact that the majority of the botanists in attendance were Americans, and that a very large proportion—about one-half—of the papers presented were from the same source.

The Section met under the very able presidency of Professor H. Marshall Ward, of Cambridge, England, who was supported by Professor D. P. Penhallow, of McGill University; Dr. W. G. Farlow, of Harvard, and Professor F. O. Bower, of the University of Glasgow, as Vice-Presidents. The attendance was not large, although representative. Of English botanists only eight were present, including, in addition to those already named, Mr. A. C. Seward, of Cambridge; Professor F. Weiss, of Owens College, Manchester; Professor J. B. Farmer, of the Royal College of Science, London; Mr. Harold Wager, of Leeds, and Professor J. R. Green and Miss D. F. M. Berts, of Cambridge.

Among those representing American botany were noted: Dr. W. G. Farlow, Dr. Britton, Dr. Coulter, Professor Barnes, Professor Penhallow, Dr. Galloway, Dr. T. J. W. Burgess, Dr. Bessey, Dr. Arthur, Mr. Webber, Professor Green, Mr. Jeffrey and others. Exceptional interest was added to the proceedings by the presence of Professor P. Magnus, of Berlin, who also contributed a valuable paper 'On the Mycelium of a Witches' Broom Fungus' and otherwise assisted in the work of the Section.

There were twenty-one papers in all presented to the Section, representing original research in nearly all the numerous branches of botanical science. These contributions were, in most cases, of a notable character, and drew forth animated and valuable discussions. The report submitted by Professor Farmer, respecting certain investigations on the 'Fertilization of the Phæophyceæ' conducted under his supervision, already indicates that new and important facts bearing upon the relationships of this group have been obtained. The investigations continue for another year under a renewed grant from the British Association.

Mr. Harold Wager gave an account of some recent studies of the yeast plant and other species of Saccharomyces, with respect to the presence of a nucleus and its constitution in various stages of development. The nucleus in yeast has been a subject of study for the past six or eight years, and its presence, as demonstrated by some seventeen observers, is abundantly confirmed by the results obtained by Mr. Wager. The author has not been able to reach final conclusions respecting the question which has been for some time in controversy as to whether the nucleus possesses a nucleolus or not, but his researches tend to the belief that certain granular bodies in constant association with the nucleus, and which present very different conditions of aggregation at various stages of growth, may represent the nucleolus. It was further shown that, in the process of budding

the nucleus extends into the neck, where it undergoes direct division, one-half remaining in the mother cell, while the other half enters the bud; and that, in the process of spore formation, the nucleus breaks up into two, and then into four, nuclei by a very simple process of karyokinesis. Some of the phenomena observed appeared to be new in the history of nuclear division and require more extended observation, but the paper as a whole offered an important addition to our knowledge of cell life, and proved to be particularly opportune in connection with the joint discussion on the cell held by the botanists and zoologists.

The efforts originally made by Hartig, and later by Brefeld, to study the development and action of wood-destroying fungi as represented by *Stereum hirsutum*, met with failure either through lack of pure cultures or imperfect methods of treatment. Professor Ward presented an account of his own recent studies of this plant, in which he employed blocks of sterilized wood, whereby he succeeded in securing a perfect fructification and observing the plant in all stages of development. The details of the progressive destruction of the woody tissue were also dealt with, and it was shown that the lignified structure gradually yielded to the action of the fungus and passed into the condition of cellulose-like bodies, giving the characteristic iodine reaction, before final consumption. The paper was illustrated by a series of beautifully prepared lantern slides, from photographs and drawings.

Professor Penhallow contributes the results of recent studies of the species of *Picea* occurring in the eastern United States and Canada, in the course of which he showed that the red spruce which had been abandoned as a distinct species since the time of Pursh, and regarded as a form of the black spruce, must once more be restored to the status of a valid species as maintained by Lawson and later by Britton. He also pointed out that there is a well defined variety of the white spruce, hitherto unrecognized, the chief characteristics of which are to be found in the strongly glaucous, rigid, often broad and cuspidate leaves, and distinctly fetid odor which has long led lumbermen and others to designate it by the name of 'Cat' or 'Skunk Spruce.' He proposes to distinguish it by the variety name of *fœtida*.

Mr. Francis Darwin gave a preliminary account of a new method of investigating the behavior of stomata, in which he details the use of a new form of hygroscope made of thin sheets of specially treated horn or 'Chinese sensitive leaf.' One end of a narrow strip is secured to the lower surface of a block of cork, and the angle to which the free end rises becomes the index of transpiration. In application, if the leaf have stomata on the under surface only, the index of the hygroscope applied to the upper side remains at zero, while on the lower side it instantly rises to an angle varying with the condition of the stomata. If these organs are widely open, the angle will be 30°–40° to a horizontal line; if the stomata are closed, the reading will be zero on both surfaces of the leaf. With this instrument a number of well known facts in the physiology of the stomata can be easily demonstrated.

Mr. H. J. Webber, of the U. S. Department of Agriculture, detailed the results of recent studies on the spermatozoids of *Zamia*. By means of a series of beautifully prepared sections he demonstrated the occurrence of unusually large spermatozoids, which, together with their flagellæ, may be seen without difficulty with an ordinary pocket lens. The paper throws new light upon our conception of the sexual elements of the Gymnosperms, and will doubtless serve as a powerful incentive to greater activity in the study of this group of plants.

Among other notable features of the meeting were a joint discussion, together with the zoologists, on the Cell; a public lecture on Fossil Plants by Mr. A. C. Seward, who, since the death of Williamson, has been recognized as the leading paleobotanist in Great Britain; and joint action with the Sections of Zoology and Physiology for the establishment of a biological station in the Gulf of St. Lawrence. While it is intended that such a station shall be primarily designed for economic ends in connection with the fisheries, it is hoped that opportunities may be offered for a limited number of students to pursue special investigations relative to both animal and plant life, and thus to supplement the work of larger stations, such as that at Woods Holl.

The special interest of the Section centered in the presidential address, which dealt in a very masterly manner with the progress of botanical science during the latter half of the Victorian reign. The address was a very noteworthy one from several points of view, though chiefly as an important historical summary. While it would be difficult and altogether unsatisfactory to attempt an abstract of a paper so rich in facts, it may be pointed out that it gave the strongest evidence to show the great dependence of important commercial undertakings and economic processes upon data derived from modern scientific botany, as also the very close relations which exist between chemistry and botany as now known. The address will form a useful key to a much wider literature, and deserves the careful perusal of the specialist as well as the general morphologist.

D. P. P.

MARINE BIOLOGICAL LABORATORY.

A STATEMENT TO THE CORPORATION FROM THE TRUSTEES.

THE annual meetings of the Corporation will hereafter be held at Woods Holl in August instead of at Boston in November, and absent members can now vote by proxy. The Board of Trustees has been enlarged to twenty-seven members, and the new Board, it is believed, fairly represents nearly all sections of this country and Canada. The closer cooperation of all institutions of learning is actively encouraged.

These changes will make possible the attendance of a large number of members, at annual and special meetings, who have been unable to reach Boston during the month of November, and there are already signs of increasing interest in the institution over a much wider area. The members will be glad to learn that, at the recent meeting of the British Association in Toronto, Dr. Dohrn, head of the unrivalled station at Naples, took occasion to speak as from personal knowledge in terms of warm commendation of the work at Woods Holl. The past summer has been highly satisfactory; but the Trustees have been hampered by lack of funds for needed repairs and renewals, and, to some extent, for current expenses. At least $1,000 should be raised before resuming work next summer, and there remains a debt of about $4,700 incurred for the erection of new buildings. This debt should be cancelled in order that a clear balance sheet may be shown before undertaking several most desirable extensions of the plant, some of which are urgently needed. Salaries should be increased, and greater inducements offered to the strong corps of instructors and workers whose collaboration has enabled the institution to attain its present position in the scientific world. Moreover, there is no assurance of permanence in an institution of this nature until it shall have acquired a sufficient endowment or maintenance fund, independent of its land, buildings and equipment (which now represent an investment of over $33,000), to relieve it from danger of extinction by one or more sea-

sons of small attendance. The Endowment Fund now amounts to over $3,500 and has been carefully husbanded, but it should be increased to at least $50,000. And the special funds, the Lucretia Crocker Fund for Scholarships and the Library Fund, may profitably be added to.

One effect of the recent changes in the By-laws will be, or may be, to diminish the special interest in and sense of responsibility for the Laboratory heretofore shown in the city of Boston and its immediate vicinity, to which, as is well known, the institution owes its initial impulse and much continuous and generous support. In appealing, as they do now, to a wider constituency, the Trustees are in no wise unmindful of the debt which the cause of science and of sound learning owes to this intelligent and kindly support in the past, some of which support, as they are assured, will hereafter be extended, with unwearied generosity, from the same locality. The Laboratory now looks to the country at large for its main sources of income and upon all the corporate members, in whose hands the recent changes have placed the entire control, rests the correlative duty of supporting the work. With power comes responsibility.

The Trustees, therefore, have decided to raise the annual dues of members of the Corporation to two dollars ($2.00). The fiscal year now begins on the second Tuesday in August, and this sum is due for the year ending August 9, 1898. Members of the Corporation will kindly forward it, together with all back dues, to the Treasurer, D. Blakeley Hoar, 220 Devonshire St., Boston, Mass.

For the reasons given above, the Trustees also appeal to the members of the Corporation to send with their annual dues such further sums, however small, as the means and interest of each in the work may inspire. All contributions will be duly noted in the annual report which is in course of preparation and will be issued early in the coming year. A contribution of not less than $100 entitles the donor to a life membership, exempt from annual dues, or, at his option, to nominate a person to occupy a private room in the Laboratory, free of charge, during one season. A contribution of $50 entitles the donor to a free scholarship, exempt from tuition fees, during one season. Contributions of smaller amounts will be gratefully received and duly acknowledged.

The forthcoming report will show fully all the recent changes in the organic law of the Association, and will be sent to all members in good standing.

By order of the Trustees,

HENRY F. OSBORN, *President*,
H. C. BUMPUS, *Secretary*,
D. BLAKELEY HOAR, *Treasurer*,
C. O. WHITMAN, *Director*.
EDWARD G. GARDINER, *Chairman of Executive Committee*,
JAMES I. PECK, *Assistant Director, Executive Committee*,
CAMILLUS G. KIDDER, *Executive Committee*.

All matters relating to scientific administration should be addressed to Professor C. O. Whitman, University of Chicago, Chicago, Ill. All applications for membership, to the Secretary, Professor H. C. Bumpus, Brown University, Providence, R. I. All dues and subscriptions, to the Treasurer, D. Blakeley Hoar, 220 Devonshire St., Boston, Mass.

A NEW LABORATORY DISH.

IN the laboratory of the college we use for routine work the paraffin method almost exclusively. The blocks of tissue are infiltrated in the usual manner, and the sections cut with the Ryder or Minot microtome. The student cuts his sections and fastens them on to the slide by means of Ole-

macher's combined water albumen method, a combination, with certain improvements, of the methods of Gaule and Mayer. These are then placed in the drying oven at a temperature of 37° C. for from 12 to 24 hours, until all the water is evaporated, the paraffin and section having, during the evaporation of the water, straightened out perfectly. The slide is now gently warmed until the paraffin, which has a melting point of 45° C., begins to melt, when it is thrust into kerosene, which in ten minutes completes the removal of the paraffin. The excess of kerosene is wiped off, the slide washed with a few drops of alcohol and then placed in a dish of alcohol; from this dish of alcohol the stain is proceeded with as usual. If the tissue has been hardened in corrosive sublimate it is necessary to carry the cemented section through diluted tincture of iodine to remove the mercurial salt; this is followed by washing in alcohol when the section is ready for staining. The stains are conveniently kept in large salt-mouthed bottles into which the slides are placed for staining, mordanting, dehydrating and clearing. It is usual for the student to take from 5 to 10 slides through the various solutions, at one time, and, in so doing, he not uncommonly scratches the section off of one slide by rubbing it against another. This difficulty arises, no matter whether the method of Gaule, Suchannek's modification of Gaule's method, Gulland's modification of Gaule's method, or, what is better, Heidenhain's water method, be used. Even using any of the collodion methods does not permit us to escape this danger. In order to overcome this, the writer sought very carefully through the dishes which have been designed by various workers, but failed to find anything which was ideally available. True, Ranvier has designed a rack upon which a number of slides may be supported, but this is entirely too cumbersome for general laboratory use, and besides involves a large amount of fluid, which makes it an expensive luxury. With these points in view, I have devised a dish which is expected to overcome some of the above difficulties.

The inside measurements of the dish are $3\frac{1}{2}$ inches in height, 1 inch square at the bottom, $1\frac{3}{8}$ inches square—three inches from the bottom, and $1\frac{3}{4}$ inches in diameter at the top, which is round and closed by means of a ground, grooved, Stender cover, which, of course, fits air-tight. In order to render the dish stable, the base is the broadest and heaviest part, measuring nearly $2\frac{1}{2}$ inches in diameter. Extending upward from the bottom of the inside of the dish, on two opposite sides, are eight ribs, four on each side, forming between them three grooves sufficiently wide to admit, in each groove, two slides of ordinary thickness. There can, also, be placed in the outside groove, between the outside ribs on each side and the inside of the dish two slides. This gives the dish, for ordinary purposes, convenient and not crowded, accommodation for eight slides standing on end; or, if the sections be not large and the slides not thick, four slides may be placed outside of the ribs, two on each side back to back.

An ordinary Stender dish requires about 120 cc. of fluid to immerse a slide sufficiently to cover a section cemented to its center. The above dish requires less than $\frac{1}{3}$ of that amount to secure an equivalent degree of immersion. Of course, these dishes vary slightly in their capacity, as all pressed glassware does; such a variation, however, does not amount to more than from 10 to 15 cc.

Where, for reasons of economy, or otherwise, it may be desirable to close the top of the dish by means of a cork or rubber stopper, the expense may be materially reduced. When closed by means of a glass cover, as described above, and shown in the

illustration, the cover and the dish will each bear the same number cut in glass, so that the student, working at his desk, may easily avoid mixing the covers which would not only be detrimental by mixing incompatible fluids; but, as each lid can be ground only to fit the dish which accompanies it, exchanged lids will not fit tightly.

In order to facilitate cleaning and to avoid inaccessible corners, all the corners are rounded.

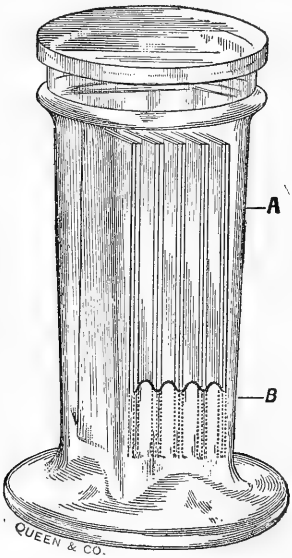

FIG. 1.—This cut is about $\frac{2}{3}$ of the exact size of the dish. At A can be seen ten (10) slides, placed back to back and passing down between the ribs at B. Since this figure was drawn the width of the base has been increased, so that the base is now the width as shown in Fig. 2.

The advantages claimed for the dish are: (1) Convenience, in that a number of slides can be safely handled at one time. (2) Great economy in the reagents; not only is the amount used less than is required by the use of Stender dishes, but in case, as will not uncommonly happen with students, anything occurs which ruins the contained fluid the loss may be materially less. (3) Solidity: no other dish of the same height and the same capacity possess the same solidity. (4) Contained fluids are prevented from evaporating by the tight-fitting top. This is not secured in the Naples dish.

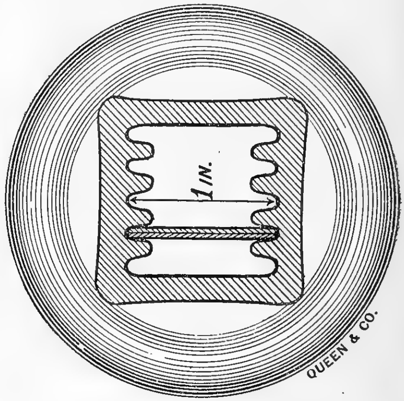

FIG. 2.—This represents a transverse section of the dish at the point marked B in Fig. 1. In this view we are looking down into the dish from above; the ribs and the intervening grooves are shown. The two arrows mark the position in which the ribs are lying and the two points, between which it is exactly 1 inch. Just to the left of the arrow is shown a transverse section of two slides placed back to back, as is usually done for staining.

I desire to express my appreciation of the help given me by Messrs. Queen & Co. in securing working drawings from which the above cuts have been made.

W. M. L. COPLIN.
JEFFERSON MEDICAL COLLEGE.

NOTES ON INORGANIC CHEMISTRY.

THE address of Professor William Ramsay, President of the Chemical Section of the British Association at Toronto, was out of the usual order. It was entitled 'An

undiscovered gas,' and narrated a search for an element with the atomic weight of 20, lying in the periodic system between helium and argon. Many 'triads' are found in the periodic system, with a difference in atomic weight of about 36 between the extremes, viz.: fluorin, chlorin, manganese, 19–55; oxygen, sulfur, chromium, 16–52; nitrogen, phosphorus, vanadium, 14–51.4, etc. If argon has an atomic weight of 40 and helium of 4 there might be expected a triad here, with a middle element of atomic weight about 20. Professor Ramsay and his assistant, Mr. Travers, made a diligent search for this element, which would, like argon and helium, probably be an indifferent gas. The gases from various minerals and mineral springs were carefully examined in vain. Helium was then fractioned by diffusion through porous plates. After 180 diffusions two fractions were obtained, the larger portion having a constant density of 1.98, that is pure helium, while the smaller portion had a variable density, and was finally proved to be helium with a small portion of argon. This search also proved fruitless. The non-existence of the gas is, however, not proven; helium itself in fergusonite, one of the minerals which yields it in reasonable quantity, is present only to the extent of 33 parts in 100,000, and if the new gas, as is by no means improbable, occurs far less abundantly than helium it will be a work of extreme difficulty to separate it from helium or argon.

IN the last *Chemical News*, G. G. Boucher describes a possible new element in cast-iron. He has found it to the extent of a few thousandths per cent. in the residues left after dissolving iron in sulfuric acid. The metal seems to possess some of the reactions of tungsten and of antimony, but has not yet been identified with any known element.

J. L. H.

SCIENTIFIC NOTES AND NEWS.

MEETING OF THE TRUSTEES OF THE MARINE BIOLOGICAL LABORATORY.

A MEETING of the Trustees was held at Woods Holl, Mass., upon Friday, September 10th. Thirteen members of the Board were present, including the Director, Professor Whitman; Professor Clarke, of Williams; Professor Macfarlane, of Pennsylvania; Professor Osborn, of Columbia; Mr. E. G. Gardiner, of Boston; Professor Bumpus, of Brown; Professor Penhallow, of McGill; Professor Metcalf, of Baltimore; Professor Patten, of Dartmouth; Professor Conklin, of Pennsylvania; Professor Morgan, of Bryn Mawr; Professor Peck, of Williams; and Mr. C. G. Kidder, of New York. The first business was the election of a President in place of Professor Farlow, of Harvard, resigned, and Professor Osborn, of Columbia, was chosen by ballot. Mr. D. Blakeley Hoar, of Boston, was elected Treasurer in place of Mr. Laurence Minot, resigned, and a resolution was passed gratefully acknowledging Mr. Minot's long and generous services to the Laboratory during the past four years. Professor Bumpus, clerk of the corporation, was elected Secretary. According to the new By-Laws, the business of the Trustees will be largely transacted by an Executive Committee, which consists of the principal officers of the Association and three members at large. This Committee was constituted for the coming year as follows: at large, Messrs. Gardiner, Peck and Kidder; and *ex officio*, Messrs. Osborn, Whitman, Bumpus and Hoar. The powers of the Executive Committee were carefully defined and limited, and this Committee was instructed to keep formal record of all its business and report to the Trustees at each meeting. A very full report of the financial condition of the Laboratory was received from the retiring Treasurer, Mr. Laurence Minot, and presented, with an analysis of the receipts and expenditures of the last season, by Mr. Kidder. It was shown that the Laboratory is practically self-supporting, but that the interest and other general charges cause an annual deficiency, which must be met by special subscription. The report of the Director was deferred until the next meeting of the Board. Two important Committees were chosen,

namely, upon Collegiate Cooperation as follows: Professor Libbey, of Princeton, Chairman; Professors Whitman, Macfarlane, Penhallow, Gardiner, Mall and Osborn; also a Committee upon Admission to Membership in the corporation, Professor T. H. Morgan, of Bryn Mawr, Chairman; Dr. E. G. Conklin, Dr. J. P. McMurrich, Dr. W. F. Ganong, Dr. E. G. Gardiner and Miss Katharine Foot. It was decided to hold the next full meeting of the Board at Ithaca, during the meeting of the American Society of Naturalists in December, and to issue the annual report immediately thereafter.

THE JOHNS HOPKINS BIOLOGICAL STATION IN JAMAICA.

WE have received from Mr. J. E. Duerdon, curator of the Jamaica Institute at Kingston, some notes regarding the researches undertaken this summer at the Marine Laboratory at Port Antonio under the charge of Professor J. E. Humphrey, whose sad death we were recently compelled to record. The party, twelve in number, secured two well-lighted rooms in the Titchfield Hotel of the Boston fruit company for a laboratory which afforded accommodation for eight tables, the necessary apparatus and reagents being brought from the University Laboratory. From the shallow waters around the harbor collections have been made in most of the various groups of animals, while the land has also been scoured for representatives of the fauna and flora. It was not found possible to carry on much dredging. In the facilities for collecting and in the richness of forms met with, the locality has been shown to surpass Port Henderson in many ways; though, owing to the continuous absence of a smooth sea about the margin of the coral reefs, Port Antonio compares unfavorably for reef work with the conditions to be met with, for some hours each morning, at the Port Royal Cays near Port Henderson.

Professor Humphrey was giving special attention to the shell-perforating algæ or sea-weeds and to the embryology of certain groups of the flowering plants, particularly among the latter to those of the pepper and ginger families. Dr. F. S. Conant continued investigations begun by him last summer upon the *Cubo-medusæ*, a rare group of jelly-fish of which two species have been found in extraordinary abundance in Jamaican waters. The chief object of investigation this season has been the function of the sensory organs of the jelly-fish, and material has been prepared with especial reference to a study of the changes, under the influence of light and darkness, in the pigment or coloring matter of the retina of the eyes. Dr. H. L. Clark has been engaged in a continuation of the work which he also began last summer on the Echinoderms (star-fish, sea-eggs, sand-dollars, sea-cucumbers, etc.), of the island, giving especial attention to the Holothurians or 'sea-cucumbers,' forms of life which are very abundant around Jamaica. Over fifty species of the group of the Echinoderms have now been collected by him and other workers, some of which are possibly new to science. Mr. Sudler has been studying the life history of *Lucifer*, one of the small crustaceæ; Mr. Greve, Ophiurius, or sea stars, and Mr. Berger, especially pseudo-scorpions. Collections have been made by Mr. A. Fredholm, of the Smithsonian Institution, Mr. Wilson and others. Mr. Duerdon was allowed the facilities of the laboratory and made a study of the Actiniaria.

THE CONFERENCE ON THE SEAL FISHERIES.

THE British Foreign Office has issued a blue book of 130 pages containing the correspondence with the United States government respecting the seal fisheries in Behring Sea. Lord Salisbury, replying to Secretary Sherman's despatch of May 10th, sent a short note to Ambassador Hay on July 28th. We reproduce this note, as it shows that the conference in Washington is intended to be strictly scientific in character.

"I have to state that her Majesty's Government are willing to agree to a meeting of experts, nominated by Great Britain, Canada and the United States, in October next, when further investigations to be made on the islands during the present season will have been completed.

"The object of the meeting would be to arrive at correct conclusions respecting the numbers, condition and habits of the seals frequenting the Pribylov Islands at the present time, as compared with several seasons previous and subsequent to the Paris award.

"It seems to her Majesty's Government that Washington would be the most suitable place for such meeting.

"The other portions of Mr. Sherman's despatch, in so far as they require any reply from her Majesty's Government, have been answered by anticipation in despatches which I addressed to her Majesty's Ambassador at Washington on April 2 and May 7 last, and which have been communicated to the Government of the United States."

Russia and Japan have signified their intention of being represented at the conference on the invitation of the United States. The United States will be represented by ex-Secretary John W. Foster and ex-Assistant Secretary Charles S. Hamlin. It has been arranged that President Jordan, of Stanford University, and his assistants, as well as the British scientific experts, shall appear personally before the conference to give the results of their investigations.

GENERAL.

THE Tenth Annual Winter Meeting of the Geological Society of America will be held at McGill University, in the city of Montreal, on December, 29, 30, 31, 1897. Details of the meeting will be announced in a circular to be issued by the Secretary, Professor Herman LeRoy Fairchild, about November 1st.

THE Berlin Academy of Sciences has made an appropriation of 3,000 Marks to Professor B. Hagen, Frankfurt, for the publication of an anthropological atlas; one of 1,500 Marks to Professor Kohen, Greifswald, for mineralogical researches, and one of 800 Marks to Professor R. Bonnet, Greifswald, for anatomical researches.

THE Dutch Academy of Sciences at Harlem has proposed seventeen subjects for papers to be presented before the beginning of next year. A gold medal is offered in each subject, or, in its place, 500 florins, with an addition of a further 500 florins in special cases. The essays may be in English. The details may be secured from the Secretary of the Academy, Professor Bosscha, Harlem.

LORD KELVIN has returned to New York from the Pacific coast and is at present the guest of Mr. John Bottomley, at Southampton, L. I. He proposes to make another short visit to Canada, and after visiting Mr. Westinghouse at Lennox will return to Great Britain.

WE learn from *Natural Science* that Dr. Henry Woodward, keeper of the department of geology in the British Museum (Natural History), has been permitted by the Treasury to retain his office for another two years. According to the rules of retirement in the civil service, his term of service would have expired next November.

MR. PERCY EMARY has been elected Secretary of the Geologists' Association, of London.

MR. HENRY W. SAGE, President of the Board of Trustees, of Cornell University, died at Ithaca, on the night of September 17th, at the age of eight-three years. Mr. Sage had given more than one million dollars to Cornell University and had been a generous donor to other educational and public institutions.

WE regret to record the death, in Assam, on July 29th, of Samuel Edward Beal, at the age of sixty-two years. He had made contributions to a wide range of sciences, including geography, astronomy, philology and agriculture.

SIR EVERETT MILLAIS, the author of numerous publications on scientific dog-breeding, and at one time editor of the *Stockkeeper*, died at Shepperton, on Tuesday, 7th. Sir Everett introduced into England the Basset hounds whose pedigrees Dr. Galton recently used for his important study on heredity.

MR. R. T. GUNTHER has gone to Lake Urumiya, on the Persian frontier, with a view to studying the fauna of the lake.

THE extensive collections of fossils made by Mr. F. E. Gurley, Danville, Ill., formerly State Geologist, is offered for sale.

THERE has just been added to the Philadelphia Museums a laboratory of tests and technology for the examination and analysis of raw and manufactured products.

COL. YOUNG, United States Army, acting Superintendent of the Yellowstone Park, has made a report to the Secretary of the Interior, stating that black bears and coyotes have multiplied so rapidly in the Park as to become annoying, and recommends capturing some of the bears for zoological gardens and killing some of the coyotes. He states that some of the people

living near the Park object to the protection of wild animals in their vicinity.

Mr. J. G. Jack opened, on September 18th, a course of lectures at the Bussey Institution, Arnold Aboretum. The lectures are popular in character and are followed by field meetings in the Aboretum. Subsequent lectures will be given on the following subjects: September 22d, maples and cherries; September 29th, thorns, locusts and hollies; October 2d, ashes and sumachs; October 6th, walnuts and hickories; October 9th, cornels and viburnums; October 13th, elms; October 16th, oaks.

The September number of the *American Naturalist* is the first to be edited by Dr. Robert P. Bigelow, of Boston, assisted by an Editorial Board, the names of whose members are not given, and a number of associate editors. To these have been added since the last issue of the journal, Messrs. G. Baur, C. E. Beecher, D. H. Campbell, J. H. Comstock, W. M. Davis, D. S. Jordan, C. Palache, H. M. Richards, W. E. Ritter, F. Russell, W. Trelease, S. Watasé. The strong hand of Professor Cope will be greatly missed in the *Naturalist* as elsewhere, but the continued usefulness of the journal appears to be assured under its new management. There is undoubtedly room in America for a monthly journal devoted to the natural sciences, in addition to the special journals devoted to a single science. With the *American Journal of Science* occupied more especially with the physical and geological sciences, the *American Naturalist* for the natural sciences and special journals for each of the sciences, America is admirably provided with the means of publication so essential for the advancement of science.

We quoted recently an editorial article from the *Journal of Geology*, on the debasement of the Missouri Geological Survey. The current number of the *American Geologist* also contains an editorial on the subject, from which it appears that Governor Stevens appointed a board consisting of political workers of the lowest type, Professor E. M. Shepard, of Drury College, Springfield, the only scientific member of the board, having resigned, and that the State Geologist appointed by them has no scientific qualifications of any sort. The records and cabinets of the Survey, which have been accumulating for the past eight years, under the present law have been consigned to the attic of an old building; all field work has been abandoned and several pieces of work, almost ready for publication, have been thrown aside. The work of the Survey at present appears to consist of drawing the usual salaries from the State Treasury. We believe that public sentiment, when expressed, is sufficient to prevent the subversion of science and education to politics, but it is often difficult to secure the expression of this sentiment, especially in cases which appear to be local in character.

From the *Sydney Morning Herald*, *Natural Science* condenses the following information regarding the second expedition to make deep borings into the coral atoll of Funafuti, which set sail from Sydney on June 3rd: Toward the expense of the expedition, Miss Eadith Walker, of Yaralla, has contributed £500; the government of New South Wales has lent a diamond drill; the Hon. Ralph Abercromby has furnished an oil-engine at a cost of £100; the Hon. H. C. Dangar and Professor T. P. Anderson Stuart have provided a fine boat; the Royal Society, London, contributes £100 directly, and probably another £100 through its coral-boring committee; finally, the London Missionary Society has offered to bring the party back to Sydney in September. The expedition is under the auspices of the Royal Geographical Society of Australasia, and its leader is Professor T. W. E. David, of Sydney. He and Mr. G. Sweet, of Melbourne, are going at their own expense, and will take charge of the borings. Mrs. David accompanies them as store-keeper and botanical collector. Mr. W. Poole, an engineer of Sydney University, will manage the light boring apparatus, and will be aided by Mr. Woolnough, who also takes charge of the zoological collecting. These gentlemen give their services free. The large diamond drill is in charge of Mr. Hall, a foreman of considerable experience, who has under him two sub-foremen and three drill-workmen. In view of the difficulties already met with at Funafuti, a special boring plant has been provided under the direction of Chief-Inspector W. H. J. Slee, and weighs over 25 tons. The main bore, on the

central island of Funafuti, will be begun with a standpipe having an inside diameter of 6 inches, and the lining pipe at first is to be 5 inches inside diameter. If, at two or three hundred feet, the friction should become too great, 4-inch pipes will be lowered inside these. It is thought that the foundations of the atoll will be reached between 200 and 500 feet, but the apparatus taken permits of a depth of 1,000 feet being reached. The core obtained will be forwarded first to the Royal Society of London, which will return one-half to the Royal Geographical Society of Australasia. The expedition will also make smaller borings on the sand cay in the middle of the lagoon, will conduct dredging operations for Sydney University and the Australian Museum, and will collect samples of sea-water for Professor Liversidge to examine for gold.

THE Philadelphia Normal School has this year established a psychological laboratory equipped for studying the senses and mental processes. Ten years ago there were only two psychological laboratories in America; at present they form an integral part of nearly all our universities and larger colleges. Their extension to normal schools is a forward step of importance in educational methods.

PSYCHOLOGICAL laboratories will probably also be established soon in hospitals for the insane, in asylums for the defective classes and in prisons. A beginning has been made in several places, but the first well equipped laboratory is now being established in the Illinois Eastern Hospital, under the direction of Dr. William O. Krohn, lately professor of psychology in the University of Illinois. A laboratory of this character will be of great practical value to the patients in the asylum, and may also be expected to make valuable contributions to psychology. As an organ for the publication of its scientific work, the Illinois hospital is about to establish a laboratory bulletin, which will appear at least four times a year. Subscriptions, $2.00, may be sent to the Hospital at Hospital, Ill.

AMONG papers announced to be read at the next meeting of the Australasian Association for the Advancement of Science at Sydney next Christmas are the following: 'The Classification of Eucalypts,' by J. G. Luckman; 'A Statistical Account of Australian Fungi,' by D. M'Alpine; 'The Algæ of Victoria,' by H. T. Tisdell; 'Flowers of the Order Proteaceæ,' by J. Shirley; 'Underground Fungi of Tasmania,' by L. Rodway; 'Australian Oceanography,' by T. W. Fowler; 'On the Formation and Structure of Coral Reefs,' by J. J. Wild; 'The Dialectic Changes of the Indo-Polynesians,' by the Rev. S. Ella; 'The Oceanic Peoples,' by E. Tregair; 'The Ancient Geography of the Maoris' and the 'Geographical Knowledge of the Polynesians,' by S. Percy Smith; 'The Mythology of the Efotese,' by the Rev. Dr. Macdonald; 'Old Samoa' and 'Australian Cave Paintings,' by the Rev. J. B. Stair; 'The Pankuma Natives,' by the Rev. F. J. Paton; 'Notes from Ambrom,' by the Rev. Dr. Lamb; 'The Tongans' and 'The Tongan Language,' by the Rev. J. E. Moulton; 'Ancient Maori Rites and Customs,' by Mr. Elsdon Best; 'The Food of the Ancient Maoris,' by the Rev. J. G. Hammond; 'Anthropometric Data, taken from School Children at Randwick,' by Jas. A. Dick; 'The Characteristics of Australian and other Diamonds,' by E. W. Streeter. The sub-committee of the council appointed to consider the matter of excursions, entertainments, visits to works, etc., has not yet completed its arrangements, but a harbor excursion had been decided upon, and two popular lectures, with possibly a third one, for workingmen, also a concert, at the University, and a conversazione by the Royal Society.

AN International Congress against alcoholism met at Brussels from August 30th to September 3d. It was under the patronage of King Leopold, and was presided over by the Minister of Agriculture.

THE sixth session of the International Institute of Statistics was opened at St. Petersburg by the Grand Duke on August 30th, holding its sessions simultaneously with those of the International Geological Congress. Numerous papers were presented dealing with military anthropometry, criminal statistics, the production of the precious metals, agricultural products, etc. Dr. Körösey, director of the statis-

tical bureau at Buda-Pesth, presented a plan for a simultaneous census of the population of the world in 1900.

THE steamship *Hope*, with Lieutenant Peary and the several scientific parties who accompanied him, arrived at Sydney, C. B., on September 20th. Lieutenant Peary has secured the large Cape York Meteorite destined for the American Museum of Natural History.

A PROPOSITION has been made for the establishment of an agricultural experiment station in Madagascar for the introduction of foreign plans of economic value and the study of those native to the island.

IT is stated in *Nature* that Mr. C. Michie-Smith, the Government Astronomer at Madras, in his reports for the year ending March 31st, says that, as regards the staff, the government has sanctioned the revival of the appointment of a chief assistant. The past year has been conspicuous by the great amount of heavy rain, and both the director's and assistants' houses have suffered considerably. Observations for time have, as usual, been carried on, and the investigation for the determination of the divisions error of the Meridian Circle has been completed, no less than 72,192 micrometer readings being employed. The Madras Catalogue has further advanced, and the mean places for the first sixteen hours have been deduced. Proposals have been sanctioned for observing the total eclipse of the sun next January, and Karad has been fixed upon as the most suitable station.

IN an address on 'Medical Botany,' presented before the Section of Materia Medica, at the recent meeting of the American Medical Association, and printed in the Journal of the Association, Professor Trelease states that while botany is still taught, to a certain extent, in medical colleges and schools of pharmacy, an analysis of the appropriateness of this study in the curriculum of either school has led him to the conclusion that for the physician it is to be regarded as an accomplishment rather than a necessity, inasmuch as in the medical practice of to-day prepared drugs and fluid extracts are prescribed, rather than the crude material, which in any event rarely comes under the physician's own observation, his knowledge dealing with the physiological rather than the physical properties of the remedial agents employed by him. While the pharmacist still has some occasion for discriminating between crude drugs, Professor Trelease concludes that even for him the botanical knowledge required is rather that of pharmacognosy than of botany in the ordinary sense; and the opinion is expressed that a knowledge of medical botany, in the old sense, is to-day essential rather to the expert of the manufacturing house than to either the physician or the pharmacist. Attention, however, is called to that branch of medical botany which has recently come into nearly all of the better equipped medical schools, dealing with the bacteria of disease, although even here it is argued that the study is rather for the expert than for the everyday practicing physician.

THE committee of the British Association appointed to report on the elucidation of the life conditions of the oyster under normal and abnormal environment, including the effect of sewage matters and pathogenic organisms, presented at Toronto a report on the green disease, drawn up by Professor Herdman and Professor Boyce. They conclude by stating that there can by no doubt that Ryder, in America, about 1880, investigated the same kind of green oyster with which they are dealing. He showed that the green coloring matter was taken up by the amœboid blood-cells, and that these wandering cells containing the pigment were to be found in the heart, in some of the blood-vessels and in aggregations in 'cysts' under the surface epithelium of the body. He describes the color (in the ventricle) as a 'delicate pea-green,' and states that it is not chlorophyll nor diatomine; he suggests that it may be phycocyanin or some allied substance. The committee have now shown that it is due to a copper compound, and consider that Ryder came nearer to what they now consider to be the truth than any previous investigator has done. He was trying to show that the color was derived from the food. Carazzi has recently suggested that the color (this, it must be remembered, is in the Marennes oyster), due to iron, is derived from the bottom on which the oyster is lying. The committee have tried numerous experiments in feeding oysters on iron and

copper salts, both soluble and insoluble, of various strengths, and also in keeping oysters on a bottom of iron or copper salts —including rusty iron, old copper and copper fillings—but in none of these experiments (the full details of which will be published later) have they got sufficiently consistent and continuous results to enable them to determine whether or not the animal obtains its copper from the contents of the alimentary canal or from the water through the surface of the body. These experiments and observations are still being carried on. They add that the green oysters containing copper are found in some localities where there can be no question of copper mines or old copper from ships' bottoms, and suggest that the pigmentation may be due to a disturbed metabolism whereby the normal copper of the body becomes stored up in certain cells.

UNIVERSITY AND EDUCATIONAL NEWS.

IT will be possible for Columbia University to open its academic year at its new site on November 4th, though there may be some delay in certain of the laboratory courses. It is noteworthy that of the six buildings now erected, two are for general university purposes, a library and university hall (which at present contains only the powerhouse and gymnasium), while the four other buildings are for the sciences, Schermerhorn Hall for the natural sciences, Havermeyer Hall for chemistry, and halls for physics and engineering. These buildings for the sciences have been erected at a cost of over $1,200,000, and demonstrate the importance of the place now occupied by science in a modern university.

AT the opening exercises of Dartmouth College, President Tucker stated that the plans are well formulated for the proposed new physical laboratory, the result of the $75,000 bequest of the late Charles T. Wilder, of Lebanon, N. H. The committee has set apart $50,000 for its erection and $20,000 for maintenance. Additional appropriations have been made for an observatory, foundations for which will be laid at once.

OF the colleges that opened last week, Dartmouth, Lafayette and Dickinson report increases in the entering classes, which are 185, 106 and 60 respectively. The classes at Union and Beloit are smaller than usual.

THE Hon. William L. Wilson, formerly member of Congress and Postmaster-General, was inaugurated as President of Washington and Lee University, Lexington, Va., on September 15th. Addresses were made by President Gilman, Johns Hopkins University; Chancellor Kirkland, Vanderbilt University, and Professor Cameron, in the place of President Patton, Princeton University. President Wilson made an inaugural address.

THE Rev. James G. K. McClure, a Presbyterian clergyman, has been elected President of Lake Forest University.

AT Union College Mr. Frank S. Thompson, A.B. (Princeton), has been appointed assistant in physics, and Dr. A. A. Tylor, A.B. (Lafayette) and Ph.D. (Columbia), instructor in biology.

DR. W. E. THOMSON has been appointed professor of physiology at Anderson's College, Glasgow.

PROFESSOR CARL FRIEDHEIM, of Berlin, has been appointed professor of inorganic chemistry in the University at Bern, and Dr. Rodet professor of bacteriology at the University at Lyons.

DISCUSSION AND CORRESPONDENCE.

TYPES IN NATURAL HISTORY AND NOMENCLATURE OF RODENTS.

TO THE EDITOR OF SCIENCE: Three communications have recently appeared in SCIENCE, directly or indirectly relating to work of my own, and I would ask your permission to say a few words concerning them.

The first two are Mr. Charles Schuchert's paper on 'Types in Natural History*, and Dr. Merriam's† critique on it, and it is to the latter I would first refer.

With characteristic emphasis Dr. Merriam scorns Mr. Schuchert's suggestions for further names to represent different classes of types, and incidentally speaks of 'several obsolete

*SCIENCE, V., p. 636, April 23, 1897.

†SCIENCE, V., p. 731, May 7, 1897.

terms which have never been used, as far as I am aware, even by the man who proposed them.' This statement is not quite correct. 'The man who proposed them,' myself, has already used them several times in print, oftener still in labeling and registering specimens, and has every intention of continuing the practice. Nor is he the only one who has done so. Moreover, had none used them as yet, in print, four years is rather a short time in which to consider obsolete terms admittedly proposed only for occasional use. The clear expression by such words of the exact relations of the specimens under discussion to the original description has been found of so much value by those who have used them that it is easy to sympathize with any one dealing with the classes of types that Mr. Schuchert refers to, wishing to have equally handy names by which to speak of them.

Mr. Schuchert has proposed to alter the definition of a *paratype* so that it should only apply to such specimens as are described or measured in the original description. This seems by no means an improvement, as the idea of a paratype is that it is one of the specimens whose examination induced the author to found a new species. In what way he worded his description, which specimens he mentioned and which he did not, in no way affect this central idea. Moreover, it is just the more aberrant individuals, and the extremes in measurement, that would be likely to be mentioned, while those that are best and most representative as paratypes would tend to be passed over in silence.

Probably Mr. Schuchert's '*plastotype*' will be of use to paleontologists and others having occasion to deal with casts, but I fail to see the benefit of his terms *hypotype* and *genotype*, of which the former is too general to be of much definite use, while the latter is based on a confusion of ideas, as while the type of a species is a *specimen*, that of a genus is a *species*, so that no *specimen* can be typical of a *genus*.

The objection to 'hypotype' as being too general and covering too many specimens of different origins applies even more strongly to Lord Walsingham and Mr. Durrant's proposed extension* of *metatype* to cover *any* specimen named by the original author, whether topotype or not. Many a museum worker, who has to name large series of specimens from all sorts of localities, must constantly put under one of his own names specimens which may be anything but typical, and it would be absurd to call the whole of a museum series of a common animal 'metatypes' merely because the name of the species happened to have been proposed by the person who determined the specimens. Probably this result of their proposal had not presented itself to the authors referred to. But after reducing 'metatype' to its original sense, Walsingham and Durrant's term '*homotype*' might suitably be employed for any specimens that had been compared with the type, such specimens being, I believe, looked upon by entomologists with a respect which, in view of the difficulty of a proper comparison, mammalogists find a little hard to understand. But, as in other cases, if entomologists find the word useful, by all means let them use it, and let not those who don't want the word object to its use by those who do.

Lastly, may I express my pleasure at the advantage mammalogical nomenclature has gained by Mr. Palmer's critique* on my recent arrangement of rodents. Every zoological paper nowadays has two sides, a real and a nomenclatural, and it so happens that the nomenclatural side of the paper discussed is particularly susceptible of improvement, partly owing to the fact that the prospect of the appearance of Mr. Palmer's own list of mammalian genera made it obvious that any labor expended in this direction would be largely wasted, and partly because my own views of nomenclature underwent a radical change just as the paper was being printed, so that some names could be altered in accordance with the newer views, and others not.

To the omitted genus *Fiber*, *Dasymys* Peters† may be added, and may be placed at 43*a*, while *Nectomys*, also of the same author, should, as elsewhere pointed out, be restored to full rank, coming at 74*a*. It also proves that *Chiruromys* Thos., should give way to *Pogonomys* M. Edw.

* Merton Rules of Nomenclature, p. 13, 1896.

* SCIENCE, VI., p. 103, July 16, 1897.

† MB. AK. Berl., 1875, p. 12.

which, instead of being a synonym of *Uromys*, should take the former's place at 52.

One change which I myself pointed out in 1895, but forgot in 1896, has escaped the lynx eyes of Mr. Palmer, namely, that *Pygeretmus* Gloger * (1841) antedates and supersedes *Platycercomys* Brandt (1844), No. 117 of the list.

In what has been called the real part of the paper, I doubt if Mr. Palmer's criticisms on the suppression of the *Lophiomyidæ* and the separation of the *Spalacidæ* and *Bathyergidæ* would have been made had he ever compared the teeth—practically identical—of *Lophiomys* and *Cricetus cricetus*, or realized to what an extent similar fossorial habits may mask real differences by a superficial resemblance, so that the two families referred to, really incomparably more different in essentials than the Americen *Geomyidæ* and *Heteromyidæ*, have yet become so alike externally that zoologists of an earlier generation naturally thought them to be nearly allied.

But on these and other points further criticism is much to be desired, and I can only repeat how fortunate it is that my mistakes and omissions in the nomenclatural part of the paper should have had the advantage of revision by such an authority on the subject as Mr. Palmer.

OLDFIELD THOMAS.

MARRIAGE BY CAPTURE IN ARABIA.

Antar is a Bedouin romance reputed to have been written by Asmai, one of the learned men of the court of Haroun-al-Raschid, shortly before the beginning of the ninth century.† From the translation by Terrick Hamilton (London, 8vo., 1820), Vol. IV., pp. 388–9, the following description of an early Arabian marriage custom is quoted. The custom is a well known one. Asmai's explanation of it is new to me.

"Now, there was a certain curious custom current among the Arabs at that period. The night on which a bridegroom should wed his wife they brought a quantity of camel pack-saddles and heaped them one upon another, decorating them with magnificent garments. Here they conducted the bride, and having seated her on high, they said to the bridegroom, "Come on, now, for thy bride!" And the bridegroom rushed forward to carry her off, whilst the youths of the tribe, drawn up in line, right and left, with staves and stones in their hands, as soon as the bridegroom rushed forward, began beating and pelting him and doing their utmost to prevent his reaching his wife. If a rib or so were broken in the affair it was well for him; if he were killed it was his destiny.

"But should he reach his wife in safety, the people quitted him and no one attempted to approach him. ('I inquired about this circumstance,' says Asmai, 'and what it was they were about.' 'Asmai,' they answered, 'the meaning of this is to exhibit the bride to the warriors, that should her husband die, anyone else might take a fancy to her and take her off.')"

So far as my reading goes, the explanation of marriage by simulated capture, which is given in the last sentence, is entirely novel.

EDWARD S. HOLDEN.

LICK OBSERVATORY,
August 15, 1897.

* Naturgesch., p. 106.

† It is, in fact, a compilation of the XIIth century.

SCIENTIFIC LITERATURE.

The Foundations of Geometry. By B. A. W. RUSSELL. Cambridge: The University Press. 1897. Pp. xvi + 201.

Here is a book especially opportune, on a subject of transcendent interest. The author's mathematical equipment is refreshingly sound, and his metaphysical results are delightfully suggestive, even where the mathematician may feel constrained to return as verdict 'not proven.' So much the more to be regretted is it that the Chapter I., 'A Short History of Metageometry,' should open with a glaring error, as follows: "The liquefaction of Euclidean orthodoxy is the axiom of parallels, and it was by the refusal to admit this axiom without proof that Metageometry began. The *first* effort in this direction, *that of Legendre*, was inspired by the hope of deducing this axiom from the others."

Mr. Russell cites Halsted's Bibliography of Hyper-Space and Non-Euclidean Geometry (1878), but can evidently never have seen it, since its first page speaks of 'The enormous

number of unsatisfactory attempts to prove this postulate,' and states that Sohncke gives a list of 92 authors on the subject before 1837, and that Perronet Thompson gave in English an account of like attempts before 1833, the very year our author cites for Legendre.

Mr. Russell goes on to say :

"Parallels are defined by Legendre as lines in the same plane, such that, if a third line cut them, it makes the sum of the interior and opposite angles equal to two right angles. He proves without difficulty that such lines would not meet."

But so had every school boy in the subject, since this is part of Euclid, Book I, Prop. 28:

"Similarly he can prove that the sum of the angles of a triangle cannot exceed two right angles, and that if any one triangle has a sum equal to two right angles all triangles have the same sum."

But these very demonstrations were published just a century before Mr. Russell's '*first* effort,' in 1733, by Saccheri.

Mr. Russell proceeds to speak of 'The originator of the whole system, Gauss,' and then says: "In 1799, writing to W. Bolyai, Gauss enunciates the important theorem that in hyperbolic geometry there is a maximum to the area of a triangle."

How utterly misleading, nay, fantastic, is this statement will appear on quoting the letter from 'Halsted's Science Absolute of Space,' 4th edition, Austin, 1896, which our author cites. Gauss says:

"I very much regret that I did not make use of our former proximity to find out *more* about your investigations in regard to the first grounds of geometry; I should certainly thereby have spared myself much vain labor, and would have become more restful than any one, such as I, can be, so long as on such a subject there yet remains so much to be wished for.

"In my own work thereon I myself have advanced far (though my other wholly heterogeneous employments leave me little time therefor), but *the* way, which I have hit upon, leads not so much to the goal which one wishes and which you assure me you have reached, as much more to making doubtful the truth of geometry.

"Indeed, I have come upon much, which with most no doubt would pass for a proof, but which in my eyes proves as good as NOTHING.

"For example, if one could prove that a rectilineal triangle is possible, whose content may be greater than any given surface, then I am in condition to prove with perfect rigor all geometry.

"Most would, indeed, let that pass as an axiom ; I not ; it might well be possible that, how far apart soever one took the three vertices of the triangle in space, yet the content was always under a given limit.

"I have more such theorems, but in none do I find anything satisfying."

From this letter it is perfectly clear that in 1799, so far from having the remotest idea of a hyperbolic geometry, or any non-Euclidean geometry, Gauss was still trying to prove that Euclid's is the only non-contradictory system of geometry and that it is the system of the external space of our physical experience. The first is false; the second can never be proved. But that both Gauss and W. Bolyai continued for the next five years to pound away in attempts to do the impossible, we have now obtained demonstrative evidence, in recovering a treatise finished and sent to Gauss by W. Bolyai in 1804.

In a great casket at Maros-Vásárhely all the unpublished papers of Bolyai János are preserved. All were placed freely at my disposal on my pilgrimage to this shrine of the non-Euclidean geometry. There, with extended researches anticipating the discoveries of Cayley and Klein in this subject, is an autobiography of János containing extracts from two letters written by Gauss to W. Bolyai (Farkas) and of transcendent importance as freeing János forever from the calumny again repeated by Mr. Russell where he says:

p. 12. "Gauss was, as we have seen, the inspirer of Wolfgang Bolyai. Wolfgang appears to have left to his son, Johann, the detailed working out of the hyperbolic system."

Nothing could be more false.

János, wholly unaided, discovered by himself the non-Euclidean geometry and taught it to Wolfgang, who transmitted it to Gauss. The two letters quoted by János are one before and one after this transmission.

This cry from the dead for tardy justice has since been shown exactly accurate by my friend, Fr. Schmidt, of Budapest, finding that the originals of these letters in the handwriting of Gauss still exist at Göttingen. The first is dated November 25, 1804, in answer to a letter

from W. Bolyai of September 16, 1804, accompanied by a Latin treatise, *Theoria parallelarum.*

It read as follows: "Now * * * yet somewhat about your geometric communication. I have read through your treatise with great interest and attention, and am right delighted at its really profound keenness. But you do not wish my empty praise, which also might seem in a measure partial because your train of ideas has very great resemblance to the way I formerly sought the untieing of this Gordian knot and vainly seek till now. You wish only my candid, open judgment. And this is, that your procedure does not give me satisfaction. I will seek, with as much clearness as I can, to bring to light the stone of stumbling which I still find therein (and which also again pertains to the same *group* of rocks wheron my attempts have hitherto been wrecked).

"I have indeed yet ever the hope that those rocks some day, and even before my end, will grant a thoroughfare. Meanwhile I have now so much other business on hand that I at present cannot think thereon, and, believe me, it will heartily delight me if you precede me and attain to overmaster all obstacles. I would, then, with inmost joy, do all in my power to make your service current and put it in the light.

* * * * * * * * *

Could you prove $dke = ekf = fkg$, etc., then would the thing be perfect. But this theorem is indeed true, only difficult to prove rigorously without already presupposing the theory of parallels. * *
You have my candid judgment. I have given it, and I repeat that it would genuinely delight me if you overcome all difficulties."

Here we see, with startling clearness, that in 1804 both Gauss and W. Bolyai (Bolyai Farkas) believe that Euclid's Parallel-Postulate can be proven, and indeed are racing to demonstrate it.

Before the next letter the unaided genius of the son, Bolyai János, has created the new universe, has found out all about it, mapped it, and proved Euclid's Postulate forever indemonstrable.

In transmitting in print to Gauss the immortal treatise of his son János, the most marvellous two dozen pages in the whole history of human thought, the father, Farkas, writes on June 20, 1831:

"My son is already First Lieutenant in the Engigineering Corps, and will soon be Captain, a handsome youth, a virtuoso on the violin, a fine fencer and brave, but has often dueled, and is still altogether too wild a soldier—but also very refined—light in darkness and darkness in light, and an impassioned mathematician with very rare gifts of mind. At present he is in the garrison at Lemberg—a great admirer of you—capable of understanding and appreciating you. At his desire, I send you this little work of his. Have the goodness to judge it with your sharp, penetrating eye, and to write your high judgment unsparingly in your answer, which I ardently await. It is the first beginning of my work, which is under the press. I would gladly send with this the first volume, but it is not yet out.

"According to my view, is in the work of my son, u (namely, where a first does not cut the b) geometrically constructed; whence, however, is not determined how great u is, from O on up to R (that excluded, this included).

"Yet everything in geometry is either dependent on u or not; (*e. g.*) spherical trigonometry is in § 26 settled as independent of it. * * *

"At the end he also shows that if u not $= R$, then the circle can be squared."

Thus we see that the treatise sent to Gauss on June 20, 1831, was the immortal Appendix just as published. The Gordian knot, at which Gauss himself had for years tried in vain, was here forever gloriously untied.

After waiting six months the anxious father tries again, and on January 16, 1832, once more sends Gauss the work of János, saying in the accompanying letter:

"My son was not present when his little work was printed. He had printed the errata (which follow); in order to be less burdensome to you, I have corrected the most with a pen.

"He writes from Lemberg that he has since simplified and made more elegant many things, and has proven the impossibility of determining *a priori* whether Axiom XI be true or not."

To this, on March 6, 1832, comes from Gauss at length an answer as follows:

* * * "Now somewhat about the work of your son:

"If I thus begin 'that I dare not praise it' you will a moment wonder; but I cannot otherwise; to praise it would mean to praise myself. For the whole content of the book, the way your son has hit out and the results to which he is led, are identical almost throughout with my own meditations, made in part already 30–35 years ago. In fact, I am thereby extremely delighted. My intention was to let nothing be known during my lifetime of my own work, of which moreover until now little has been put on paper. Most men have not at all the right sense for

what is here in question, and I have found only few people who received with special interest that which I communicated to them. In order for that one must first have felt right keenly what really is lacking, and about that most men are wholly indistinct.

"On the other hand, my intention was, with time, to put all on paper, so that it at least would not hereafter perish with me.

"Therefore am I greatly pleased that this trouble can now be spared me, and it is most highly delightful to me that the son of just my old friend is he who in so remarkable a way has anticipated me.

"I find his notations very pregnant and abridging. Yet I believe it would be good to establish for many chief ideas not merely symbols or letters, but definite names, and I have already since long thought of some such names.

"So long as one thinks through the thing only in immediate intuition, one needs no name or symbol; these are first necessary, if one wishes to be comprehensible to others. So, for example, the surface which your son calls F could be called a Parasphere, the line L a Paracykle: they are, in fact, spheres or circles of infinite radius. Hypercykle could be named the complex of all points which have like distance from a straight with which they lie in a plane; even so Hypersphere. Yet those are all only unimportant incidents; the main thing is the matter, not the form.

* * * * * *

"Just exactly in the impossibility to decide *a priori* between Σ and S lies the clearest proof that Kant was wrong to maintain, Space is *only Form* of our intuition."

About the other independent discoverer of the non-Euclidean geometry, Lobachévski, Gauss writes to Schumacher, November 28, 1846, without a word of reference to Bolyai, as follows:

"I have lately had occasion to reread the opuscule of Lobatschewsky, intitled: *Geometrische Untersuchungen zur Theorie der Parallellinien.* This opuscle contains the elements of the geometry which would exist and development of which would form a rigorous chain, if the *Euclidean* geometry were not true. * * * You know that since fifty-four years (since 1792) I share the same convictions, without speaking here of certain developments which my ideas on this subject have since received. Therefore, I have not found in the work of Lobachevski any fact new to me; but the exposition is wholly different from that which I had projected, and the author has treated the matter with a master hand and with the veritable geometric spirit."

How reconcile these letters with that of 1804? And since one says that Bolyai's exposition is identical with that of Gauss, while the other declares Lobachévski's wholly different from that, how reconcile them with the statement of Mr. Russell, p. 11: "Very similar [to Lobachévski's] is the system of *Johann Bolyai*, so similar, indeed, as to make the independence of the two works, though a well-authenticated fact, seem all but incredible?"

This letter of 1846 shows no hint of that other sort of non-Euclidean geometry which Riemann gave in his wonderful Probevorlesung, 'Ueber die Hypothesen welche der Geometrie zu Grunde liegen,' June 10, 1854.

But this dissertation was not published until 1867, so that the waters of oblivion seemed to close over it as over the works of Bolyai and Lobachévski.

Mr. Russell should not have omitted in his text all mention of Hoüel, for Hoüel it was who resurrected the non-Euclidean geometry, beginning with his own essay on the fundamental principles of geometry, published in 1863 at Greifswald. (See his life in the *Amer. Math. Monthly*, April, 1897.)

But not to give too much space to actual slips in history we must jump to the second of Mr. Russell's four chapters, 'Critical account of some previous philosophical theories of geometry:'

"The importance of geometry in the theories of knowledge which have arisen in the past can scarcely be exaggerated."

The author believes that the usual forms of non-Euclidean geometry, the hyperbolic, the double elliptic and the single elliptic are the only logically self-consistent systems, and so says: "I shall contend that those axioms, which Euclid and Metageometry have in common, coincide with those properties of any form of externality which are deducible, by the principle of contradiction, from the possibility of experience of an external world."

We see at once that pure projective geometry must be of supreme weight for him.

It is a treat to see our author overwhelm the apparent subordination of the non-Euclidean spaces by the introduction of different measures of distance. This was the painful mistake of

Emory McClintock in his article 'On the non-Euclidean geometry' in the Bulletin of the N. Y. (Amer.) Math. Soc., Vol. II., pp. 21–33, which reached the pitiful conclusion (p. 32): "The chief lesson to be obtained from all non-euclidian diversions (sic) is that the distinguishing mark of euclidian geometry is fixity of distance—measurement."

Mr. Russell, with equal deftness, puts in pillory the gross blunder made by Andrew W. Phillips and Irving Fisher, professors in Yale University, in the note on p. 23 of their Elements of Geometry, where they say: "Lobatchewsky in 1829 proved that we can never get rid of the parallel axiom without assuming the space in which we live to be very different from *what we know it to be through experience.*"

By experience, of course, we can never know or prove our space to be other than a non-Euclidean space with a comparatively large constant. How unexpected, then, the error of Professor H. Schubert, of Hamburg, in the *Monist*, Vol. VI., No. 2, p. 295, where he says:

> "Let me recall the controversy which has been waged in this century regarding the eleventh axiom of Euclid, that only one line can be drawn through a point parallel to another straight line. The discussion merely touched the question whether the axiom was capable of demonstration solely by means of the other propositions, or whether it was not a special property, *apprehensible only by sense-experience*, of that space of three dimensions in which the organic world has been produced."

After 20 years' study of writers on the non-Euclidean geometry, the present reviewer cannot recall even one who was ever silly enough to think that the exact equality of the angle-sum of a rectilineal triangle to two right angles was apprehensible by sense-experience, or could ever be known through experience.

This new Yale geometry also makes the old *petitio principii* of defining a straight line as the *shortest* distance between two points. This our author treats in his third chapter, p. 167:

> "We are accustomed to the definition of the straight line as the *shortest* distance between two points. * * * Unless we presuppose the straight line, we have no means of comparing the lengths of different curves and can, therefore, never discover the applicability of our definition."

In projective geometry any two points uniquely determine a line, *the straight*. But any two points and their straight are, in pure projective geometry, utterly indistinguishable from any other point-pair and their straight. It is of the essence of metric geometry that two points shall completely determine a spatial quantity, *the sect*. If our author had used for this fundamental spatial magnitude this name, introduced in 1881, his exposition would have gained wonderfully in clearness.

Both the accepted popular and the accepted mathematical definition of 'distance' make it always a number, as, *e. g.*, the Cayley-Klein definition: "The distance between two points is equal to a constant times the logarithm of the cross ratio in which the line joining the two points is divided by the fundamental quadric."

It is the misfortune of our author to use the already overworked and often misused word 'distance' as a confounding and confusing designation for a sect itself and also the measures of that sect, whether by superposition, ordinary ratio, indeterminate as depending on the choice of a unit, or projective metrics, indeterminate as depending on the fixing of the two points to be taken as constant in the varying cross ratios.

This whole book might be cited as an overwhelming vindication of the only American treatise on Projective Geometry against the attack on it made by a critic in SCIENCE, because, forsooth, it was founded and developed as *pure* projective geometry, without any quantitative ideas whatever.

Into the fourth and last chapter, 'Philosophical Consequences,' we will not here go. Suffice it to say that Projective and Metric Geometry, though eternally separate in essence, and each unable ever to absorb the other, are happily wedded, and expand joyfully ever after.

AUSTIN, TEXAS.

Sight: An Exposition of the Principles of Monocular and Binocular Vision. JOSEPH LE CONTE. New York, D. Appleton & Co. 1897. Second edition, revised and enlarged. Pp. xvi + 318. $1.50.

A revised and enlarged edition of Professor

Le Conte's book on 'Sight' is extremely welcome. It remains true now, as it was in 1880, when the first edition was published, that there is no other book in the English language covering this field. During the past year two excellent American contributions have, indeed, been made to the subject—Professor Bowditch's survey in the 'American Text-book of Physiology' and the various articles in the 'Systems of Diseases of the Eye,' by Norris and Oliver. But Professor Le Conte's book is the only treatise covering the subject of vision in English, and, in fact, in any language, with the exception of the more technical works of von Helmholtz and Aubert. While it is surprising, and not altogether creditable to the 'new psychology,' that we have only one book on the subject, it is fortunate that it is so excellent.

Professor Le Conte devotes two-thirds of his book to binocular vision. This is excessive for a text-book, but it is justified by the interest of the subject and by the important original contributions of the author. Following an introduction on the senses, the part on monocular vision includes sections on the general structure of the eye, the formation of the image, the perfect eye, defects of the eye, structure of the retina, space perception and color perception. In this part should, perhaps, be included the final chapter on the evolution of the eye, added in this edition, which, however, appears as the 7th chapter of the third part, entitled in the table of contents, 'Some abstruser points, especially in binocular vision,' and in the text, 'On some disputed points in binocular vision.'

The author has added some new matter to this first part, especially on color blindness and color perception, including a full statement of the Donders-Franklin theory. I regret the omission or brief treatment of subjects so important as the intensity of sensations, their time relations, the field of vision, illusions, the combination of colors,* etc. It is in any case evident that everything cannot be included in 100 pages, and it is a wonder that Professor Le Conte has been able to give with such clearness so much. There are several points on which I should differ with the author. For example, the explanation of 'upright vision,' which has been discussed in this JOURNAL. Professor Stratton, a colleague of Professor Le Conte's at the University of California, has since made the ingenious experiment of wearing, for several days, glasses that inverted the normal retinal image and shows how quickly adjustment is made. But it is still easier to stand on one's head and notice that the landscape is not seen inverted.

The two parts on binocular vision contain clear and concise accounts of experiments largely devised by Professor Le Conte. Making these experiments would, as the author says, be for any one an admirable culture in scientific method. Many of the experiments are valuable contributions to science, but the details are somewhat complex and cannot be made clear in a review. The reader must turn to Professor Le Conte's book, with its many new and ingenious illustrations, in order to appreciate the importance of a study of binocular vision and the great value of the author's contributions to the subject. I may note that I have recently been told by an eminent oculist that the conflicting results in the case of Listing's law found by von Helmholtz were due to unrecognized astigmatism in his eyes.

There are some points where Professor Le Conte's statements do not seem to me quite accurate. For example, he says, "We always see things double, except under certain conditions." This is scarcely correct psychology; we must learn by practice to see things double, and then usually see them double only while the experiment lasts. Professor Le Conte says, "I believe that the existence of the central spot is necessary to fixed, *thoughtful attention*, and this, again, in its turn, is necessary for the development of the higher faculties of the mind." But may not the mental faculties of those born blind be developed? There are further many subjects, such as the horopter, that I cannot regard as finally solved by Professor Le Conte, but his researches have accomplished much toward their solution and should be accepted as the basis of future work.

J. McKEEN CATTELL.

COLUMBIA UNIVERSITY.

*Fortunately some of these topics are fully treated in another admirable book in this same series, Professor Rood's 'Modern Chromatics.'

*AN UNDISCOVERED GAS.**

A SECTIONAL address to members of the British Association falls under one of three heads. It may be historical, or actual, or prophetic; it may refer to the past, the present or the future. In many cases, indeed in all, this classification overlaps. Your former presidents have given sometimes a historical introduction, followed by an account of the actual state of some branch of our science, and, though rarely, concluding with prophetic remarks. To those who have an affection for the past, the historical side appeals forcibly; to the practical man, and to the investigator engaged in research, the actual, perhaps, presents more charm; while to the general public, to whom novelty is often more of an attraction than truth, the prophetic aspect excites most interest. In this address I must endeavor to tickle all palates; and perhaps I may be excused if I take this opportunity of indulging in the dangerous luxury of prophecy, a luxury which the managers of scientific journals do not often permit their readers to taste.

The subject of my remarks to-day is a new gas. I shall describe to you later its curious properties; but it would be unfair not to put you at once in possession of the knowledge of its most remarkable property —it has not yet been discovered. As it is still unborn, it has not yet been named. The naming of a new element is no easy matter. For there are only twenty-six letters in our alphabet, and there are already over seventy elements. To select a name expressible by a symbol which has not al-

* Address to the Chemical Section, British Association for the Advancement of Science, Toronto, 1897, by the President of the Section.

ready been claimed for one of the known elements is difficult, and the difficulty is enhanced when it is at the same time required to select a name which shall be descriptive of the properties (or want of properties) of the element.

It is now my task to bring before you the evidence for the existence of this undiscovered element.

It was noticed by Döbereiner, as long ago as 1817, that certain elements could be arranged in groups of three. The choice of the elements selected to form these triads was made on account of their analogous properties, and on the sequence of their atomic weights, which had at that time only recently been discovered. Thus calcium, strontium and barium formed such a group; their oxides, lime, strontia and baryta are all easily slaked, combining with water to form soluble lime-water, strontia-water and baryta-water. Their sulphates are all sparingly soluble and resemblance had been noticed between their respective chlorides and between their nitrates. Regularity was also displayed by their atomic weights. The numbers then accepted were 20, 42.5 and 65; and the atomic weight of strontium, 42.5, is the arithmetical mean of those of the other two elements, for $(65+20)/2 = 42.5$. The existence of other similar groups of three was pointed out by Döbereiner, and such groups became known as 'Döbereiner's triads.'

Another method of classifying the elements, also depending on their atomic weights, was suggested by Pettenkofer, and afterwards elaborated by Kremers, Gladstone and Cooke. It consisted in seeking for some expression which would represent the differences between the atomic weights of certain allied elements. Thus, the difference between the atomic weight of lithium, 7, and sodium, 23, is 16; and between that of sodium and of potassium, 39, is also 16. The regularity is not always so conspicuous; Dumas, in 1857, contrived a somewhat complicated expression, which, to some extent, exhibited regularity in the atomic weights of fluorine, chlorine, bromine, and iodine, and also of nitrogen, phosphorus, arsenic, antimony and bismuth.

The upshot of these efforts to discover regularity was that, in 1864, Mr. John Newlands, having arranged the elements in eight groups, found that when placed in the order of their atomic weights, 'the eighth element, starting from a given one, is a kind of repetition of the first, like the eighth note of an octavo in music.' To this regularity he gave the name 'The Law of Octaves.'

The development of this idea, as all chemists know, was due to the late Professor Lothar Meyer, of Tübingen, and to Professor Mendeléeff, of St. Petersburg. It is generally known as the 'Periodic Law.' One of the simplest methods of showing this arrangement is by means of a cylinder divided into eight segments by lines drawn parallel to its axis; a spiral line is then traced round the cylinder, which will, of course, be cut by these lines eight times at each revolution. Holding the cylinder vertically, the name and atomic weight of an element is written at each intersection of the spiral with a vertical line, following the numerical order of the atomic weights. It will be found, according to Lothar Meyer and Mendeléeff, that the elements grouped down each of the vertical lines form a natural class; they possess similar properties, form similar compounds, and exhibit a graded relationship between their densities, melting points, and many of their other properties. One of these vertical columns, however, differs from the others, inasmuch as on it there are three groups, each consisting of three elements with approximately equal atomic weights. The elements in question are iron, cobalt and nickel; palladium, rhodium and ruthenium; and platinum,

iridium and osmium. There is apparently room for a fourth group of three elements in this column, and it may be a fifth. And the discovery of such a group is not unlikely, for when this table was first drawn up Professor Mendeléeff drew attention to certain gaps, which have since been filled up by the discovery of gallium, germanium and others.

The discovery of argon at once raised the curiosity of Lord Rayleigh and myself as to its position in this table. With a density of nearly 20, if a diatomic gas, like oxygen and nitrogen, it would follow fluorine in the periodic table; and our first idea was that argon was probably a mixture of three gases, all of which possessed nearly the same atomic weights, like iron, cobalt and nickel. Indeed, their names were suggested, on this supposition, with patriotic bias, as Anglium, Scotium and Hibernium! But when the ratio of its specific heats had, at least in our opinion, unmistakably shown that it was molecularly monatomic, and not diatomic, as at first conjectured, it was necessary to believe that its atomic weight was 40, and not twenty, and that it followed chlorine in the atomic table and not fluorine. But here arises a difficulty. The atomic weight of chlorine is 35.5, and that of potassium, the next element in order in the table, is 39.1; and that of argon, 40, follows, and does not precede, that of potassium, as it might be expected to do. It still remains possible that argon, instead of consisting wholly of monatomic molecules, may contain a small percentage of diatomic molecules; but the evidence in favor of this supposition is, in my opinion, far from strong. Another possibility is that argon, as at first conjectured, may consist of a mixture of more than one element; but, unless the atomic weight of one of the elements in the supposed mixture is very high, say 82, the case is not bettered, for one of the elements in the supposed trio would still have a higher atomic weight than potassium. And very careful experiments, carried out by Dr. Norman Collie and myself, on the fractional diffusion of argon, have disproved the existence of any such element with high atomic weight in argon, and, indeed, have practically demonstrated that argon is a simple substance and not a mixture.

The discovery of helium has thrown a new light on this subject. Helium, it will be remembered, is evolved on heating certain minerals, notably those containing uranium; although it appears to be contained in others in which uranium is not present, except in traces. Among these minerals are clèveite, monazite, fergusonite, and a host of similar complex mixtures, all containing rare elements, such as niobium, tantalum, yttrium, cerium, etc. The spectrum of helium is characterized by a remarkably brilliant yellow line, which had been observed as long ago as 1868 by Professors Frankland and Lockyer in the spectrum of the sun's chromosphere, and named 'helium' at that early date.

The density of helium proved to be very close to 2.0, and, like argon, the ratio of its specific heat showed that it, too, was a monatomic gas. Its atomic weight, therefore, is identical with its molecular weight, viz., 4.0, and its place in the periodic table is between hydrogen and lithium, the atomic weight of which is 7.0.

The difference between the atomic weights of helium and argon is thus 36, or 40 — 4. Now there are several cases of such a difference. For instance, in the group the first member of which is fluorine we have:

Fluorine	19	
		16.5
Chlorine	35.5	
		19.5
Manganese	55	

In the oxygen group—

Oxygen	16	
		16
Sulphur	32	
		20.3
Chromium	52.3	

In the nitrogen group—

Nitrogen	14	
		17
Phosphorus	31	
		20.4
Vanadium	51.4	

And in the carbon group—

Carbon	12	
		16.3
Silicon	28.3	
		19.8
Titanium	48.1	

These instances suffice to show that approximately the differences are 16 and 20 between consecutive members of the corresponding groups of elements. The total differences between the extreme members of the short series mentioned are—

Manganese—Fluorine	36
Chromium—Oxygen	36.3
Vanadium—Nitrogen	37.4
Titanium—Carbon	36.1

This is approximately the difference between the atomic weights of helium and argon, 36.

There should, therefore, be an undiscovered element between helium and argon, with an atomic weight 16 units higher than that of helium, and 20 units lower than that of argon, namely 20. And if this unknown element, like helium and argon, should prove to consist of monatomic molecules, then its density should be half its atomic weight, 10. And pushing the analogy still farther, it is to be expected that this element should be as indifferent to union with other elements as the two allied elements.

My assistant, Mr. Morris Travers, has indefatigably aided me in a search for this unknown gas. There is a proverb about looking for a needle in a haystack; modern science, with the aid of suitable magnetic appliances, would, if the reward were sufficient, make short work of that proverbial needle. But here is a supposed unknown gas, endowed, no doubt, with negative properties and the whole world to find it in. Still, the attempt had to be made.

We first directed our attention to the sources of helium—minerals. Almost every mineral which we could obtain was heated in a vacuum, and the gas which was evolved examined. The results are interesting. Most minerals give off gas when heated, and the gas contains, as a rule, a considerable amount of hydrogen, mixed with carbonic acid, questionable traces of nitrogen, and carbonic oxide. Many of the minerals, in addition, gave helium, which proved to be widely distributed, though only in minute proportion. One mineral—malacone—gave appreciable quantities of argon; and it is noteworthy that argon was not found except in it (and, curiously, in much larger amount than helium), and in a specimen of meteoric iron. Other specimens of meteoric iron were examined, but were found to contain mainly hydrogen, with no trace of either argon or helium. It is probable that the sources of meteorites might be traced in this manner, and that each could be relegated to its particular swarm.

Among the minerals examined was one to which our attention had been directed by Professor Lockyer, named eliasite, from which he said that he had extracted a gas in which he had observed spectrum lines foreign to helium. He was kind enough to furnish us with a specimen of this mineral, which is exceedingly rare, but the sample which we tested contained nothing but undoubted helium.

During a trip to Iceland, in 1895, I collected some gas from the boiling springs there; it consisted, for the most part, of air, but contained somewhat more argon than is usually dissolved when air is shaken with water. In the spring of 1896 Mr. Travers and I made a trip to the Pyrenees to collect gas from the mineral springs of Cauterets, to which our attention had been directed by Dr. Bouchard, who pointed out that these gases are rich in helium. We examined a number of samples from the

various springs, and confirmed Dr. Bouchard's results, but there was no sign of any unknown lines in the spectrum of these gases. Our quest was in vain.

We must now turn to another aspect of the subject. Shortly after the discovery of helium its spectrum was very carefully examined by Professors Runge and Paschen, the renowned spectroscopists. The spectrum was photographed, special attention being paid to the invisible portions, termed the 'ultra-violet' and 'infra-red.' The lines thus registered were found to have a harmonic relation to each other. They admitted of division into two sets, each complete in itself. Now, a similar process had been applied to the spectrum of lithium and to that of sodium, and the spectra of these elements gave only one series each. Hence, Professors Runge and Paschen concluded that the gas, to which the provisional name of helium had been given, was, in reality, a mixture of two gases, closely resembling each other in properties. As we know no other elements with atomic weights between those of hydrogen and lithium, there is no chemical evidence either for or against this supposition. Professor Runge supposed that he had obtained evidence of the separation of these imagined elements from each other by means of diffusion; but Mr. Travers and I pointed out that the same alteration of spectrum, which was apparently produced by diffusion, could also be caused by altering the pressure of the gas in the vacuum tube; and shortly after Professor Runge acknowledged his mistake.

These considerations, however, made it desirable to subject helium to systematic diffusion, in the same way as argon had been tried. The experiments were carried out in the summer of 1896, by Dr. Collie and myself. The result was encouraging. It was found possible to separate helium into two portions of different rates of diffusion, and consequently of different density by this means. The limits of separation, however, were not very great. On the one hand, we obtained gas of a density close on 2.0; and on the other, a sample of density 2.4 or thereabouts. The difficulty was increased by the curious behavior, which we have often had occasion to confirm, that helium possesses a rate of diffusion too rapid for its density. Thus, the density of the lightest portion of the diffused gas, calculated from its rate of diffusion, was 1.874; but this corresponds to a real density of about 2.0. After our paper, giving an account of these experiments, had been published, a German investigator, Herr A. Hagenbach, repeated our work and confirmed our results.

The two samples of gas of different density differ also in other properties. Different transparent substances differ in the rate at which they allow light to pass through them. Thus, light travels through water at a much slower rate than through air, and at a slower rate through air than through hydrogen. Now Lord Rayleigh found that helium offers less opposition to the passage of light than any other substance does, and the heavier of the two portions into which helium had been split offered more opposition than the lighter portion. And the retardation of the light, unlike what has usually been observed, was nearly proportional to the densities of the samples. The spectrum of these two samples did not differ in the minutest particular; therefore it did not appear quite out of the question to hazard the speculation that the process of diffusion was instrumental, not necessarily in separating two kinds of gas from each other, but actually in removing light molecules of the same kind from heavy molecules. This idea is not new. It had been advanced by Prof. Schützenberger (whose recent death all chemists have to deplore), and later, by Mr. Crookes, that what we term the atomic weight of an

element is a mean; that when we say that the atomic weight of oxygen is 16 we merely state that the average atomic weight is 16; and it is not inconceivable that a certain number of molecules have a weight somewhat higher than 32, while a certain number have a lower weight.

We therefore thought it necessary to test this question by direct experiment with some known gas; and we chose nitrogen, as a good material with which to test the point. A much larger and more convenient apparatus for diffusing gases was built by Mr. Travers and myself, and a set of systematic diffusions of nitrogen was carried out. After thirty rounds, corresponding to 180 diffusions, the density of the nitrogen was unaltered, and that of the portion which should have diffused most slowly, had there been any difference in rate, was identical with that of the most quickly diffusing portion, *i. e.*, with that of the portion which passed first through the porous plug. This attempt, therefore, was unsuccessful; but it was worth carrying out, for it is now certain that it is not possible to separate a gas of undoubted chemical unity into portions of different density by diffusion. And these experiments rendered it exceedingly improbable that the difference in density of the two fractions of helium was due to separation of light molecules of helium from heavy molecules.

The apparatus used for diffusion had a capacity of about two litres. It was filled with helium, and the operation of diffusion was carried through thirty times. There were six reservoirs, each full of gas, and each was separated into two by diffusion. To the heavier portion of one lot the lighter portion of the next was added, and in this manner all six reservoirs were successively passed through the diffusion apparatus. This process was carried out thirty times, each of the six reservoirs having had its gas diffused each time thus involving 180 diffusions.
